It is noticeable that the variation in brightness of this star amounts to about three magnitudes, and therefore exceeds that of any Algol star hitherto discovered. Like all other Algol stars, its spectrum is of the first type. A table showing the times of minima for the remainder of the year is included in the *Circular*.

## *THE HOUSING OF THE OFFICES OF THE UNIVERSITY OF LONDON.*

THE history of the negotiations which have taken place between the Government and the Senate of the University of London, relating to the proposal of the Government to provide accommodation for the University in the Imperial Institute building, is contained in the subjoined extracts from the Report of the Special Committee appointed by the University to confer with representatives of the Treasury and of the Imperial Institute upon the matter.

At a meeting of the Senate held on December 7, 1898, a letter from Sir Francis Mowatt to the Vice-Chancellor (Sir Henry Roscoe) was read, stating that it had been suggested to the Cabinet that an arrangement might be possible by which an adequate and dignified home for the University of London could be provided in the Imperial Institute buildings, subject to some extension and internal alterations, if terms could be offered which would be acceptable to the authorities of the Institute.

The terms submitted to the Senate of the University are as follows:—

"The Government will provide adequate and suitable accommodation for the University of London, as constituted by the Act of last Session, in the buildings of the Imperial Institute, such accommodation to include examination rooms and laboratories either in the building itself or in a new building to be erected immediately adjoining it.

"The Government will undertake the entire cost of the upkeep and maintenance of the buildings, including their protection from fire.

"The works necessary for providing the accommodation in the Institute buildings, corresponding to that now enjoyed by the University in Burlington Gardens—and including the new laboratories—will be put in hand at once; and the headquarters and offices of the University, as at present constituted, will be transferred from Burlington Gardens as soon as possible after the new accommodation is ready for their reception.

"The accommodation in the Institute buildings required for the teaching side of the University will be prepared in anticipation of the date at which the provisions of the Act of last Session come into full operation.

"A Committee consisting of representatives of the University, the Treasury, and the First Commissioner of Works, should be appointed forthwith to inquire and report as to the necessary alteration and adaptation of the Institute buildings for the purposes of the University."

After a brief statement of the scope and object of this offer, the discussion upon the proposals was adjourned. There seemed to be some uncertainty in the minds of certain of the Fellows as to the precise terms upon which the proposed joint occupation of the buildings of the Imperial Institute were to be arranged as between the Government on the one hand and the University and the Imperial Institute on the other. It was felt that if a statement could be made upon certain points raised in the discussion such statement would be of signal service in clearing away any misapprehension which might have arisen. The following inquiries were therefore sent to Sir Francis Mowatt, and, with the replies, were read at a meeting of the Senate on February 1:—

"1. Is it to be understood that the Government proposes to take over the whole of the present building of the Imperial Institute for the use of (*a*) the University of London, (*b*) the authorities of the Imperial Institute?

"2. Will the University (in case the proposals are carried out) be the tenants of the Government under identical conditions as to fixity of tenure, maintenance, &c., as heretofore in Burlington Gardens?

"3. Is it understood:

"(*a*) That the University will become possessed for its sole use of so much of the Institute buildings as the Government shall decide, after communication with the University of London, to be sufficient for its present and prospective accommodation?

"(*b*) That the University shall have the first use of such halls, corridors, galleries, as are necessary for carrying on its work of examination?

"(*c*) That all concerts and other entertainments in the Institute are to be abolished?

"(*d*) That a suitable entrance to the University portion of the building will be provided after due communication with the architect?

"(*e*) That all educational work of University character carried on within such portion of the building handed over to the Institute authorities shall be under the direct control of the University?

"(*f*) That proper accommodation will be provided for the University examinations in practical science either in the Imperial Institute buildings or in others to be built outside as may be decided on after further discussion?"

The reply, dated Christmas Day 1898, was as follows:—

"It is not the intention of the Government that any of the three parties should enter on the proposed inquiry with their hands tied. Their sole wish is that the University, the Institute, and the Treasury should meet and discuss whether *any*, and, if any, what arrangement is possible, under which the University could be suitably housed, and under suitable conditions, in the

present Institute buildings. If the result of the discussion is to show that no suitable arrangement is practicable, the University will be in no way prejudiced by having shown its readiness to discuss the project in a friendly spirit. It will be quite open to the Senate to make an express reservation in the above sense a condition of sending its representatives to sit on the Committee.

"The answer to the first and second questions is yes.

"As regards the third, the answers are—

"(*a*) Yes.

"(*b*) I am not sure that I quite understand the meaning of the words 'the first use,' but if the following definition will meet the views of the Senate, I can answer the question in the affirmative, viz. 'Full and exclusive use and control at all times at which the said halls are required for the purposes of examination.'

"The regulations for giving effect to this condition will be drawn up by the Treasury, who will be responsible for seeing that they are carried out.

"(*c*) The representatives of the Institute have assured me that the entertainments and concerts will not again take place, but it will be quite open to the Senate to safeguard themselves by making the discontinuance of such things a condition of their presence on the Committee.

"The answers to (*d*), (*e*) and (*f*) are in the affirmative."

The views of Convocation upon the proposals are contained in the following letter from the Clerk of Convocation to the Registrar, read at the meeting of the Senate :—

"I am directed by the Special Committee of Convocation, appointed to communicate with the Statutory Commission and the Senate, to request you to inform the Senate that the Committee having had their attention directed to the subject of the proposed transference of the University to the Imperial Institute, adopted the following resolution :—

"That, in the opinion of this Committee, the Imperial Institute would furnish an adequate and dignified home for the University, provided that the exclusive and permanent control of the whole or a distinct and sufficient portion, with an adequate entrance, and with security of tenure, be vested in the University."

On the motion of the Vice-Chancellor, seconded by Lord Kimberley, it was then resolved :

"That with reference to the correspondence between the Vice-Chancellor and Sir Francis Mowatt, the Senate do agree to join in the Conference therein mentioned upon the terms generally set forth in the correspondence, and without prejudice to the ultimate action of the Senate, and that accordingly three Fellows be nominated as a Special Committee of the Senate to serve on the Conference, and to report to the Senate the result of the Conference."

The following Fellows were nominated Members of the Special Committee :—The Vice-Chancellor, Lord Kimberley, and Sir Joshua Fitch.

At the next meeting of the Senate, on February 22, further correspondence was presented. It was announced that the Lords Commissioners of Her Majesty's Treasury had selected the undermentioned gentlemen to represent them at the Conference :—

Sir F. Mowatt and Mr. S. E. Spring Rice, both of the Treasury, and Mr. Almeric Fitzroy, Clerk of the Council.

The following Treasury Minute, dated February 16, 1899, was read :—

"The First Lord and the Chancellor of the Exchequer state to the Board that Her Majesty's Government have had under consideration the possibility of an arrangement with the authorities of the Imperial Institute whereby a dignified and suitable home may be provided in the Institute buildings at South Kensington for the University of London, as reconstituted by the Act of last Session. The accommodation would include the sole occupation and control of rooms and offices fully equal in number and dimension to those now in the possession of the Senate at Burlington Gardens ; examination rooms and laboratories either in or immediately adjoining the existing building ; and also such provision as may hereafter be needed for the full extension and development of the University under the statutes and regulations made by the Commissioners appointed by the Act.

"The First Lord and the Chancellor of the Exchequer state that, as the result of negotiations which have taken place between representatives of the University, the Institute and the Treasury, there is reason to hope that an arrangement meeting all the requirements of the several interests is now possible ; and they recommend to the Board that the authorities of the University and the Institute should be invited to nominate representatives, who will consider and report in conference with persons selected by the Treasury—

"I. Whether such an arrangement is in fact practicable.

"II. What is the amount and nature of the accommodation to be transferred.

"III. What alterations or adaptations are necessary to render it in all respects suitable to the needs of the University.

"IV. Under what conditions it should be held from Her Majesty's Government by the Senate.

"The object of the Conference would be expressly limited to furnishing Her Majesty's Government with full information upon the several points indicated above ; and the consent of the several parties to enter the Conference would not pledge them to accept any recommendation which the representatives, or a majority of them, may make.

"My Lords approve the course recommended by the First Lord and the Chancellor of the Exchequer."

The representatives of the Council of the Institute appointed to take part in this Conference were Lord James of Hereford, the Right Hon. Sir Henry Fowler, M.P., and Sir Frederick Abel.

The Conference thus constituted held several meetings at the Treasury and at the Institute, and the Committee paid repeated visits to South Kensington with a view to ascertain the exact extent and capabilities of the building, particularly of that portion of it which it is proposed to assign to the University.

On the first of these occasions the Prince of Wales met the Committee and accompanied the members through the various rooms of the Institute. His Royal Highness evinced much interest in the proposed arrangement, and expressed a strong wish to meet the requirements of the Senate and to facilitate the work and due development of the University.

At a subsequent meeting the representatives of the University were requested to draw up, for the information of their colleagues, a statement showing the nature of the accommodation needed by the University, and also the way in which the eastern portion of the building might be adapted to the use and to the future requirements of the University. In conformity with this wish the Committee prepared a memorandum, which became the basis of discussion at subsequent meetings of the Conference.

Among the points referred to in this document are the future requirements of the University. Upon this subject the representatives of the University remark :

"In considering the proposal to exchange the present building in Burlington Gardens for a portion of that now occupied by the Imperial Institute, it is necessary not only to take into account the means of supplying these serious deficiencies, but also to forecast the probable requirements of the University under its new constitution. The details of that constitution are now being settled by the Statutory Commission appointed under the provisions of the University of London Act of 1898.

"The new statutes will certainly provide for a large extension in the work and usefulness of the University, will invest it with new teaching powers, will bring it into closer relations with the principal colleges and medical schools of the metropolis, and will, without encroaching on the ordinary functions of those institutions, probably do much to encourage the development of post-graduate study and of research, under the direction of the governing body of the University, and in its central building."

With regard to the central portion of the building, the memorandum states :—

"It is evident that joint user of this neutral territory, on the part of the Institute and the University, would be for many reasons inconvenient unless the relations and claims of the two bodies are clearly defined. Otherwise frequent references to the Treasury would become necessary.

"Moreover, it is essential for the credit and for the usefulness of the metropolitan University that it should not be regarded as, in any sense, a department of another institution. It would cause grave disappointment to the Senate and to the Graduates if we were unable to report to them that the Government were sensible of the importance of this consideration, and able to give effect to it.

"It is obviously desirable that the building to be known as the University of London should have a separate entrance."

It was in relation to the neutral territory referred to that the representatives of the University felt it necessary to receive further explanations. It was at first proposed by the authorities of the Institute that a joint permanent Committee should be formed, and that while the University and the Institute respectively should be entitled to have the use of the central hall and the east conference hall on certain occasions to be specified beforehand, the occupation of the rooms on other occasions should be settled by arrangement with this Committee. But grave inconvenience and the possibility of future complications were foreseen in such an arrangement. From the first it had been impressed upon the Treasury that the relations of the University should be with the Government alone, and that any plan which assumed that the University should be either tenants or partners with another institution would certainly be unwelcome to the Senate. The Committee therefore insisted that, in accordance with the letter of Sir Francis Mowatt of Christmas Day 1898, the University should be the tenants of the Government only. As a result the following formal communication, dated May 16, was received by the Vice-Chancellor from Sir Francis Mowatt:—

"With reference to our recent discussions as to the conditions on which the Government is prepared to offer to the University improved and enlarged accommodation in the Imperial Institute building, I am authorised by the Chancellor of the Exchequer to inform you that the original intention of the Government remains unchanged, namely, to take over *all* the present building for the use of (*a*) the University of London, and (*b*) the authorities of the Imperial Institute, and that he has caused notification to this effect to be communicated to the Council of the Institute.

"I am at the same time instructed to forward to you the enclosed memorandum indicating that the University will hold direct from the Government."

The memorandum enclosed was as follows:—

"In any arrangement under which the University is invited to occupy a part of the Institute building, it will be an absolute condition that the University holds directly and solely from the Government and not in any form or degree from the Institute.

"This is true equally of the part to be occupied exclusively by the University and of the part to be occupied alternately by the University and by the Institute under arrangements to be approved by the Treasury."

The exact nature of the arrangements here referred to between the University and the Treasury, with respect to the central portion of the building, the galleries, and the east conference hall, will be fixed from time to time on the understanding that the full and exclusive use of these portions of the building will be secured for the University at all times at which they are required for purposes of examination, for the annual ceremony of the presentation for degrees, and for the meetings of Convocation. The Senate will also afford, as it has been accustomed to do during many years, accommodation to meetings and congresses of a national and international character, as well as for assemblies of graduates or others interested in the promotion of collegiate or advanced education.

Subject, therefore, to any reservation which the Treasury may make as to the use of the central portion of the main building for occasional meetings of the Imperial Institute, the building, with the exception of the west wing, will either belong exclusively to the University or will be at its disposal when required. The main entrance will be used by the University and by the Imperial Institute jointly. An additional University entrance and staircase will give access to the east wing, and will serve for candidates for examination and for other purposes.

The assent of the Council of the Imperial Institute to the Government proposals was notified in a letter dated June 5 from Lord James of Hereford to Sir Francis Mowatt.

With regard to the future appropriation of land adjacent to the building, it is understood that, in view of the probable future requirements of the University, especially in the direction of scientific and literary research and of post-graduate lectures and studies, the University will be entitled to a first claim on any vacant ground which may hereafter prove to be needed. The area thus available is very large.

It is understood that the Government is prepared to undertake the whole cost of the removal of the effects of the University to its new quarters, and that the Chancellor of the Exchequer will include in the estimates for this year a sufficient sum to meet all charges for furnishing the rooms, for adapting them to the purposes of the University, and also for effecting such structural and other changes as may be found necessary in subsequent consultation between the officers of the University and the architect of the Board of Works. At present no change is proposed in the financial arrangement by which the charges of the University for the maintenance and care of the building, the provision of stationery and stores, the salary of the officers, and the expenses of administration are borne by the Treasury, and are provided, so far as they exceed the amount received from candidates in the form of fees, by an annual vote in Parliament.

This arrangement is, however, wholly exceptional, and does not apply to any other University in Great Britain. It undoubtedly relieves the authorities of the University from all financial concern or responsibility. But it cannot be regarded as a permanently satisfactory settlement, or one which is likely to conduce to the repute and independence of the University, or to its due development in the future. It has the obvious and serious result of discouraging endowments and gifts, and of diminishing the interest which the inhabitants of London ought to take in their chief academic institutions. So long as the University is dependent for its maintenance on an annual vote in Parliament, it can hardly be expected to receive much voluntary support. Such generous gifts from private persons or from municipal bodies as have enriched the colleges of the Victoria University, and have recently been promised to the contemplated University of the Midlands, are not likely to be forthcoming in London while the University exists on its present financial basis. But it may well be hoped that under different conditions the University will evoke similar local patriotism to that which has been so conspicuously shown in Manchester, Liverpool, Leeds, Cardiff, Newcastle and Nottingham, and that the citizens of London will become conscious of a new responsibility, and will take a pride in strengthening and enlarging from time to time an institution which ought to serve as a great centre of intellectual life for the whole metropolis.

The Government has throughout this negotiation shown a strong desire to make the best provision in its power to meet the needs of the University and the wishes of the Senate and the Graduates. And, having regard (1) to the fact that the present accommodation is insufficient, and that there are no means of enlarging it upon its present site; (2) to the size and dignity of the Institute building and its capacity for adaptation and expansion; (3) to the fact that no alternative proposal for the housing of the University in a more appropriate place is likely to be made; and (4) to the consideration that the building, though not geographically central for London, is placed in the midst of a group of institutions—the Royal College of Science, the Natural History Museum, the City and Guilds of London Institute, the College of Music, and the Science and Art Galleries and Museums—which are all in various ways cognate in their objects with the purposes and work of the University, the Committee conclude by expressing the opinion that the proposal of the Government has been conceived in a fair and liberal spirit, and that it deserves the favourable consideration of the Senate.

## *PHYSICAL MEASUREMENTS IN ANTHROPOLOGY.*

THE question of the value of physical measurements is one that lies at the base of physical anthropology. Large numbers of often very extended series of measurements are continually being published, new methods are constantly being proposed and tried; but in spite of all this, it is questionable whether the value of the results obtained is proportionate to the trouble expended. Unfortunately there is variability in the methods employed, which may change according to the nationality of the investigators; some methods are complicated like those of Benedikt and Tœrœk, or, as in the case of the latter anthropologist, who takes 5000 measurements on a single skull, they may be impracticably numerous. Very precise measurement with refined instruments gives an apparent exactitude which appears to be more scientific than it really is. Preferable is the system that adopts a small number of measurements which can be readily made, and which have a better chance of being taken on a large number of subjects. The

extreme exactitude of cranial measurements, especially when based, for example, on the cephalic index only, has often led to creating imaginary races among a given people.

These and other wholesome warnings are uttered by O. Hovorka Edler von Zderas in the *Centralblatt für Anthropologie*, iii. p. 289, who also points out that there is no need to calculate indices to the first or second decimal, and he also states that in the analysis of a people one should not take account of differences of less than ten units in the index.

As all investigators are well aware, the cephalic index gives no information upon the real form of the skull; this has been well emphasised by Sergi, who has sought to establish a more rational system of skull nomenclature. M. L. Laloy supports (*l'Anthropologie*, x. p. 105) Hovorka's general contention, and refers to the clever visual analysis of the inhabitants of Bretagne by Dr. P. Topinard, which was published in the *Journal of the Anthropological Institute* (1897, xxviii. p. 99). In the last number of the *Journal* (new series, i. p. 329) Dr. Topinard gives the results of the trip which he made to Cornwall last year in order to compare the anthropological types there with those he had previously ascertained in Bretagne. But in our own country Dr. J. Beddoe has long adopted a similar method of investigation, and his acute and trained powers of observation have thrown a flood of light on the problems of the races of Britain. The methods of the *doyen* of British anthropologists are those of the field naturalist, and there are many who realise that what is generally known as "natural history," is as integral a part of biology as is the most refined laboratory technique. It is well to use one's eyes for other purposes than for reading off scales on instruments.

## *WAVE OR BILLOW CLOUDS.*

A SERIES of cloud photographs taken by Mr. Alfred J. Henry, of the United States Weather Bureau, and contributed to the *Monthly Weather Review* for February, is on several grounds specially instructive. It is too frequently the case that photographers content themselves with a single plate of a cloudy sky, which specially recommends itself to their notice by the grouping and arrangement of the vaporous patches. But in this instance we have a succession of pictures of the same clouds, showing their variation during the interval, and, moreover, taken in various azimuths at different stations, so that we get the same formation viewed from different standpoints. We regret that we can only reproduce one of the very admirable pictures that Prof. Henry has secured, It is the first of the series, and shows the typical arrangement of these clouds as they first arrested the attention of the observer. The altitude was probably that of the mean altocumulus level. Occurring as these clouds do at all possible heights above the surface, we are glad to notice that the term wave or billow, following the nomenclature of Helmholtz, is coming into use, since such a description more nearly expresses the character of the formation than do other terms which generally refer to the height alone.

We have here in the cause of the formation of these clouds an instance of the advantage of theoretical investigation over simple observation. The readings of meteorological instruments explain nothing of the origin or behaviour of atmospheric waves. Prof. Henry has recorded for us, with the care that becomes a meteorologist, that the wind was blowing steadily from the north-west with a velocity of twelve miles an hour. Rain had ceased shortly before, and the temperature, which had fallen to 34° during the night, had risen at the time at which the photograph was taken (8h. 25m. a.m.) to 36°. The direction of the parallel bands when first observed was approximately east and west. Later they took up a position about N. 80° W. to S. 80° E. In an hour and a half the typical appearance of the billow wave had passed away, leaving the sky about half covered with cirrus and cirro stratus. It is not unimportant to note, however, that the occurrence of similar weather conditions gave rise to a similar formation of clouds (also photographed) some two months later.

This is all that instrumental registration and careful observation can teach us, and possibly the slow onward movement of meteorological science is traceable to the strict adherence we have generally shown to the record of instrumental indications, rather than a confident appeal to theoretical research. But the study of such a cloud formation as that pictured here goes a step beyond the reading of instruments, and places in our hands a powerful means by which to investigate the motion of the atmosphere. It cannot have escaped general notice that this regular arrangement of streaks presents the peculiarity of covering a considerable extent of the sky, almost simultaneously. On a comparatively clear sky these strips of cloud are suddenly formed; and on the other hand, a sky uniformly covered can, in a very short space of time, break up and offer the appearance of these billow waves. This sudden origin of parallel streaks finds a complete analogy in the formation of waves over still water, when a slight wind agitates the surface, and it is seen to break into ripples over a considerable area. Von Helmholtz, working on this suggestion, has shown conclusively that these billow waves are due to the existence of air strata of different temperatures moving with different velocities, and are produced at the surfaces of separation of these various strata. Travellers in balloons have confirmed this theory from actual experiment, and have shown that at very various altitudes this peculiar formation is encountered. It may be that the billow clouds are visible to us only under peculiar circumstances of moisture, but the wave motion in the invisible air is probably a most common phenomenon, and one that plays a large part in determining our weather conditions.

Wave or Billow Clouds.

## *THE PROPOSED MAGNETIC SURVEY OF THE UNITED STATES.*[1]

THE present superintendent of the Coast and Geodetic Survey, Prof. Henry S. Pritchett, perceiving the need of expansion in the magnetic work of the Survey, has brought about the formation of a separate division, known as the Division of Terrestrial Magnetism of the United States Coast and Geodetic Survey. The chief of this division is to be Dr. L. A. Bauer, who will have full control of all magnetic work, both in the field and in the office.

The following preliminary outline will serve to give some indication of the character and scope of the work it is proposed to carry out with the enlarged opportunities.

### Secular Variation Investigations.

The best evidence of the great demand for secular variation data is the fact that, thus far, eight editions of Schott's secular variation paper have been successively issued by the Survey.

[1] Abridged from an advance proof of a paper by Dr. L. A. Bauer in *Terrestrial Magnetism*.

In all matters relating to the re-location of land boundaries, where it is frequently necessary to know the precise amount of angular change in the direction of the magnetic meridian since the first or original survey, the Coast and Geodetic Survey is recognised throughout the country as the ultimate authority. The amount of money saved to landowners by such authoritative determinations as the Survey is able to furnish, can scarcely be estimated. It certainly exceeds many times the total amount to be spent for magnetic work.

Every effort will be made in the future to multiply and verify the secular variation data, and requests for information on the part of surveyors will be encouraged in every possible manner and true meridian lines established for them.

This involves the determination of the magnetic elements, declination, dip, and intensity at various points throughout the land. Exactly how close the stations shall be to each other depends upon the special purpose to be accomplished with the means at hand, and the magnetic character of the regions involved.

A magnetic survey has peculiar difficulties to contend with; for the quantities to be experimentally determined are for ever undergoing changes—some periodic, others not periodic. A magnetic survey must, therefore, be made to refer to some particular moment of time, and such means must be taken as to enable one to reduce all the measurements, not only to the selected epoch of the survey, but also, as occasion may demand, to some other epoch in the near past or in the near future. Means must also be taken for the proper elimination of all such errors as are to be referred entirely to the particular magnetic instrument used, *i.e.* instrumental errors.

### NUMBER AND DISTRIBUTION OF STATIONS.

At how many stations it will be necessary to determine the magnetic elements? The areas of the countries at present belonging to the United States are, approximately, as follows:—

| | | |
|---|---|---|
| United States ... ... ... | 3,025,600 | square miles |
| Alaska ... ... ... ... ... ... | 577,390 | ,, |
| Hawaiian Islands ... ... ... | 6,250 | ,, |
| Porto Rico ... ... ... ... ... | 3,530 | ,, |
| Total ... ... ... | 3,612,770 | ,, |

Hence the area is equal to that of entire Europe, or about one-fifteenth of the entire land area of the globe. As magnetic surveys have been especially prosecuted in Europe, it will be of interest to note the density of distribution of the magnetic stations in two recent, fruitful magnetic surveys—viz. that of Great Britain, where there was one station to every 139 square miles; and that of Holland, embracing one station to every 40 square miles.

Suppose one station is decided upon, on the average, to every 100 square miles—an end that may be obtained some day—then the determination of the magnetic elements would be required at 30,000 stations within the United States. At the rate of 400 stations a year, the magnetic survey, as detailed as this, would require for its completion at least seventy-five years. It is not well, however, to have a magnetic survey extend over such a long interval of years. The errors incurred in reducing the observations to a common epoch would greatly exceed the errors of observation.

It is evident, then, that a very large number of observers and instruments would be required to complete the survey within a short interval, say ten years at the most, or a less detailed survey will have to be undertaken.

The plan of conducting a magnetic survey of the United States which appears to be best suited to the present conditions, and one that it is possible to carry out within a reasonably short time, is as follows:—To make first a general magnetic survey of the country with stations about twenty-five to thirty miles apart; then, as opportunities present themselves, to add stations in the magnetically disturbed areas. The observations at the "repeat stations," made from time to time, will furnish the proper secular variation corrections.

The great advantages of this plan over that of attempting a greatly detailed magnetic survey at once, the steady progress of which over the entire country, on account of its extent, would necessarily be very slow, will be readily perceived. It will be of interest, however, to point out that the plan, as briefly outlined, will make it possible, within a reasonable time, to construct two sets of magnetic maps for the same epoch, each set based upon a different distribution of the stations. An opportunity will thus be afforded, as in the case of the magnetic survey of Great Britain, to obtain some idea of the accuracy with which the isomagnetic lines can be determined. The satisfactory solution of this question will serve as a valuable guide in future magnetic work.

Various State geologists, incited by the example set by the State Geologist of Maryland, Prof. William Bullock Clark, either have already made plans, or are making plans, for detailed magnetic surveys of their respective States, in co-operation with the Coast and Geodetic Survey.

### MAGNETIC SURVEY OF OCEAN AREAS.

Provision for the determination of the magnetic elements at sea are being made. With the many vessels at the service of the Coast and Geodetic Survey, exceptional facilities for this purpose will be afforded. In fact, one of the chief duties of the Survey is the supplying of magnetic data to the mariner. From an economic standpoint this feature of magnetic work is the one really of the greatest practical importance. In recognition of this fact, the Survey vessels will hereafter take advantage of every opportunity to obtain the magnetic elements on sea and on shore.

### MAGNETIC OBSERVATORIES.

The rapid, successful, and economical execution of the plans as above briefly outlined requires the establishment, at certain points, of magnetic observatories, where the countless variations in the earth's magnetic force are continuously and automatically recorded, enabling thus the proper corrections to be applied to observations made at stations at any hour of the day.

The present plans contemplate the establishment of a magnetic observatory near Washington City—this will be the Central or Standard Observatory; another near Seattle, State of Washington; one in the Hawaiian Islands, and one in Alaska. With the co-operation of the observatories at Toronto, Mexico and Havana, and with the aid of secondary or temporary observatories established as occasion may demand, the areas to be surveyed will be fairly well covered.

It is very much to be hoped, however, that the universities and colleges in the United States will seriously consider the establishment of magnetic observatories. Many an institution which lacks the means of making a reputation in astronomical work, could still afford to inaugurate useful work in terrestrial magnetism.

The United States stands at the bottom of the list of civilised countries possessing magnetic observatories. Almost every European Power of note maintains, not only one, but several permanent magnetic observatories. France has four already established, and four additional ones in process of erection; and progressive Japan, with its small strip of territory, has six continuously operating magnetic observatories.

The recent International Magnetic Conference recommended the establishment of a magnetic observatory at the Lick Observatory. It is earnestly to be hoped that this suggestion will be carried out. It is unfortunate that the San Antonio observatory in Texas had to be abandoned. A permanent observatory should be re-established in this locality.

The scheme of work for the Coast and Geodetic Survey observatories will embrace, in addition to the regular magnetic work, observations in atmospheric electricity and of the electric currents within the earth. Such observations can be carried on with practically no additional cost, and yet add greatly to the value of the observatory work. Arrangements will likewise be entered into with the Potsdam Magnetic Observatory for the making of strictly simultaneous observations of a special character.

The plan of referring the initiation and prosecution of magnetic work in America to such a well-organised department as the Coast and Geodetic Survey, the work of which is recognised universally as of the highest order, will readily be seen to have decided advantages. In the first place, the machinery for carrying on the work is already to a great extent in existence. The observer engaged in geodetic or astronomical work can frequently include to advantage magnetic observations, and thus can often be saved the chief cost of magnetic work—the occupying of stations. Again, the care and refinement with which the geodetic and astronomical work of this bureau is carried out will ever be an incentive to keep the magnetic work of the same high order.

## UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—The following is an extract from the speech delivered at the Encaenia on the presentation of F. D. Godman, F.R.S., Trustee of the British Museum, for the degree of D.C.L., June 21.

"In ea Naturae parte quae ad animalium herbarumque varietates pernoscendas spectat neminem vel diligentius vel utilius hoc viro laborasse scitote.

Ille enim, scientiae amore instigatus, Americae quae dicitur centralis saltus silvasque una cum amico suo caro Osberto Salwino (nuper fato eheu! nobis abrepto) longis pererravit peregrinationibus atque fruges fetusque omnes ejus orbis terrarum partis adcurate investigavit.

Nec illud tacendum arbitror eundem diversi generis species illic ab ipso cura infinita collectas quum rarissimas tum etiam pretiosissimas singulari munificentia Museo nostro Britannico donasse."

THE Committee of the City and Guilds of London Institute are inviting applications for the appointment of Assistant Professor in the Department of Civil and Mechanical Engineering at the Institute's Central Technical College. Particulars of the appointment may be had of the Honorary Secretary of the Institute, Gresham College, E.C.

THE Board of Education Bill was considered by the House of Commons Committee of Ways and Means on Tuesday. It was resolved "That it is expedient to authorise the payment, out of moneys to be provided by Parliament, of a salary, not exceeding 2000*l.*, to the president of the Board of Education, and of salaries and remuneration to the secretaries, officers, and servants of the Board, in pursuance of any Act of the present Session to provide for the establishment of a Board of Education for England and Wales."

MAJOR-GENERAL SIR JOHN F. D. DONNELLY, K.C.B., retired on Monday from the Secretaryship of the Science and Art Department, after forty years in the public service. In consequence of Sir J. Donnelly's retirement, the Duke of Devonshire, Lord President of the Council, has made the following appointments:—Sir George W. Kekewich, K.C.B., the present Secretary of the Education Department, to be also Secretary of the Science and Art Department. Captain W. de W. Abney, C.B., to be the Principal Assistant Secretary of the Science and Art Department. Mr. W Tucker, C.B., to be the Principal Assistant Secretary of the Education Department.

THE Duke and Duchess of York visited Exeter on Tuesday and opened a new wing of the Albert Memorial Museum and College. The Museum became affiliated with the Cambridge University several years ago, when the Exeter Technical and University Extension College was started, with Mr. A. W. Clayden as principal. This institution, to be known in future as the Royal Albert Memorial Museum and College, is now sufficiently equipped for the requirements of a local college. In opening the new wing, the Duke of York remarked that the efficient results attained at Exeter and also at Reading seem to indicate that it is possible for the municipal authorities of towns of moderate size to establish, with the co-operation of the great universities, institutions providing for higher and technical instruction. The co-operation of the universities, with their expert knowledge, and the local authorities with their control of funds for educational purposes and their practical knowledge of local needs, cannot fail to be of the greatest advantage to the community from an educational standpoint.

## SCIENTIFIC SERIALS.

*Meteorologische Zeitschrift*, June.—On the amount of cloud in Europe during cyclonic and anticyclonic days, by Dr. C. Kassner. In this important discussion the author has investigated the cloud observations at five principal stations in Europe for twenty years (1871-90), and has followed a plan adopted by Dr. Leyst in another discussion by selecting the days in each month when the readings of the barometer were lowest or highest. These days, including the days preceding and following that on which the extreme reading occurred, are those called respectively cyclonic or anticyclonic periods. He finds that in cyclonic periods the maximum amount of cloud only occurs on the principal day in summer and autumn, while in winter and spring a large amount of cloud occurs in the evening of the preceding day as well as on the morning of the principal day. The preceding day has generally somewhat less cloud than the principal day, and almost always more than the following day. This result agrees with that deduced by the late Mr. Ley, and by the Deutsche Seewarte with respect to the distribution of cloud in cyclones. In anticyclonic periods the least cloud frequently occurs, not on the principal day, but on the preceding or following day; this is especially the case at Christiania and Pavlovsk, where the least cloud occurs before the passage of the highest barometric pressure, and then gradually increases. Generally speaking, however, the principal day is clearest, and next to this the preceding day, but not always, for at Buda-Pesth and Tiflis the day following that of the maximum barometric pressure has less cloud than the day preceding.

*Bollettino della Società Sismologica Italiana*, vol. iv., 1898, No. 9.—Old seismic instruments, by P. Tacchini, referring to an old form of the Cecchi seismograph and to Cacciatore's mercury seismoscope, recently acquired by the Central Office of Meteorology and Geodynamics at Rome, and which, with others already in the possession of the office, will form the nucleus of a seismometrical museum.—Principal eruptive phenomena in Sicily and the adjacent islands during the half-year July to December 1898, by S. Arcidiacono.—Later modifications in the electrical seismoscope of double effect, by G. Agamennone. Describes several improvements by which the instrument may be put more rapidly in working order.—Notices of earthquakes recorded in Italy (December 25 to 31, 1897), by G. Agamennone, the most important being an after-shock of the Umbria-Marches earthquake of December 27, and the Haiti earthquake of December 29.

**Royal Society**, June 15.—"The Colour Sensations in Terms of Luminosity." By Captain W. de W. Abney, C.B., D.C.L., F.R.S.

This paper deals with a determination of the colour sensations (based on the Young theory) by measuring the luminosity of the three different colour components in a mixed light which matches white. At the red end of the spectrum there is but one colour extending from its extreme limit to near C, and there is no mixture of other colours which will match it, however selected, and is, on the theory adopted, a colour which excites but one sensation. At the violet end of the spectrum, from the extreme violet to near G, the same homogeneity of light exists, but it is apparently due to the stimulation of two sensations, a red and a blue sensation, the latter never being stimulated alone by any spectrum colour. Having ascertained this, it remained to find that place in the spectrum where the blue sensation was to be found unmixed with any other sensation except white. By trial it was found that close to the blue lithium line this was the case, and that a mixture of this colour and pure red sensation gave the violet of the spectrum when the latter was mixed with a certain quantity of white. The red and the blue sensation being located, it remained to find the green sensation. The complementary colour to the red in the spectrum gave a position in which the green and blue sensations were present in the right proportions to make white, and a point nearer the red gave a point in which the red and blue sensations were present in such proportions as found in white, but there was an excess of green sensation. By preliminary trials this point was found. The position in the spectrum where the yellow colour complementary to the violet was also found. The colour of bichromate of potash was matched by using a pure red and the last-named green. To make the match, white had to be added to the bichromate colour. A certain small percentage of white was found to exist in the light transmitted through a bichromate solution with which the match was made, and this percentage and the added white being deducted from the green used, gave the luminosity of the pure green sensation existing in the spectrum colour which matched the bichromate. Knowing the percentage composition in luminosity of the two sensations at this point, the luminosity of the three sensations in white was determined by

matching the bichromate colour with the yellow (complementary to the violet) and the pure red colour sensation. From this equation and from the sensation equation of the bichromate colour already found, the sensation composition of the yellow was determined. By matching white with a mixture of the yellow and the violet, the sensation equation to white was determined. The other colours of the spectrum were then used in forming white, and from their luminosity equations their percentage composition in sensations were calculated. The percentage curves are shown. The results so obtained were applied to various spectrum luminosity curves, and the sensation curves obtained. The areas of these curves were found, and the ordinates of the green and violet curves increased, so that both their areas were respectively equal to that of the red. This gave three new curves in which the sensations to form white were shown by equal ordinates.

A comparison of the points in the spectrum where the curves cut one another, and of those found by the red and green blind as matching white, show that the two sets are identical, as they should be. The curves of Koenig, drawn on the same supposition, are mentioned, and the difference between his and the new determination pointed out.

The red below the red lithium line, as already pointed out, excites but one (the red) sensation, whilst the green sensation is felt in greatest purity at $\lambda$ 5140, and the blue at $\lambda$ 4580, as at these points they are mixed only with the sensation of white, the white being of that whiteness which is seen outside the colour fields.

"A Comparison of Platinum and Gas Thermometers, including a Determination of the Boiling Point of Sulphur on the Nitrogen Scale: an Account of Experiments made in the Laboratory of the Bureau International des Poids et Mesures, at Sèvres." By Drs. J. A. Harker and P. Chappuis. Communicated by the Kew Observatory Committee.

The present paper is the outcome of the co-operation of the Kew Observatory Committee and the authorities of the International Bureau of Weights and Measures at Sèvres, for the purpose of carrying out a comparison of some platinum thermometers with the recognised international standards.

A new resistance-box, designed for the work, and special platinum thermometers together with the other accessories needed were constructed for the Kew Committee, and, after their working had been tested at Kew, were set up at the laboratory at Sèvres in August 1897. The comparisons executed between these instruments and the standards of the Bureau may be divided into several groups. The first group of experiments covers the range $-23^\circ$ to $80^\circ$, and consists of direct comparisons between each platinum thermometer and the primary mercury standards of the Bureau. Above $80^\circ$ the mercury thermometers were replaced by a gas-thermometer, constructed for measurements up to high temperatures. The comparisons between $80^\circ$ and $200^\circ$ were made in a vertical bath of stirred oil, heated by different liquids boiling under varying pressures. For work above $200^\circ$ a bath of mixed nitrates of potash and soda was substituted for the oil tank. In this bath comparisons of the two principal platinum thermometers with the gas-thermometer were made up to $460^\circ$; and with a third thermometer, which was provided with a porcelain tube, we were able to go up to $590^\circ$. Comparisons of the platinum and gas-scales were carried out at over 150 different points, each comparison consisting of either ten or twenty readings of the different instruments.

By the intermediary of the platinum thermometers a determination of the boiling point of sulphur on the nitrogen scale was also made. The mean of three very concordant sets of determinations with the different thermometers gave $445^\circ \cdot 27$ as the boiling point on the scale of the constant volume nitrogen thermometer, a value differing only about $0^\circ \cdot 7$ from that found by Callendar and Griffiths for the same temperature expressed on the constant pressure air scale.

If for the reduction of the platinum temperatures in our comparisons we adopt the parabolic formula proposed by Callendar, and the value of $\delta$ obtained by assuming our new number for the sulphur-point, we find that below $100^\circ$ the differences between the observed values on the nitrogen scale and those deduced from the platinum thermometer are exceedingly small, and that even at the highest temperatures the differences only amount to a few tenths of a degree.

Full details as to the instruments employed and the methods adopted are given in the paper.

"On the Comparative Efficieny as Condensation Nuclei of positively and negatively charged Ions." By C. T. R. Wilson, M.A. Communicated by the Meteorological Council.

When moist air is ionised, a greater degree of supersaturation is required to cause water to condense on the positively charged ions than on the negatively charged ones. The experiments consisted in measurements of the expansion required to cause condensation in the form of drops in air initially saturated and containing ions alternately nearly all positive and nearly all negative The ratio of the final to the initial volume being indicated by $v_2/v_1$, then to cause water to condense on negatively charged ions, the supersaturation must reach the limit corresponding to the expansion $v_2/v_1 = 1 \cdot 25$ (approximately a fourfold supersaturation). To make water condense on positively charged ions, the supersaturation must reach the much higher limit corresponding to the expansion $v_2/v_1 = 1 \cdot 31$ (the supersaturation being then nearly sixfold). Thus, if ions ever act on condensation nuclei in the atmosphere, it must be mainly or solely the negative ones which do so, and thus a preponderance of negative electricity will be carried down by precipitation to the earth's surface. Experiments were carried out which appear to prove that the difference in the condensing power of positive and negative ions is not to be explained by supposing the charge of each negative ion to be, for example, twice as great as that of each positive ion. Experiments were also tried to test whether the rainlike condensation, which always takes place in moist air when the expansion $v_2/v_1 = 1 \cdot 25$ is exceeded, is due to slight ionisation of the moist air. These experiments led to the conclusion that this is not a case of condensation on ions; unless the process of producing the supersaturation itself gives rise to ionisation.

**Mineralogical Society**, June 20.—Prof. A. H. Church, F.R.S., President, in the chair.—Mr. E. G. J. Hartley gave the results of analyses of so-called plumbogummite from Roughten Gill, Georgia, and Huelgoat. The blue mineral from Roughten Gill, usually regarded as a silicate or carbonate of zinc, proved to be identical with the hitchcockite from Georgia. Both minerals have been analysed by Mr. Hartley, and shown to contain about 19 per cent. of water and 3 per cent. of carbonic acid. In a note on the optical characters, Prof. Miers finds that these two minerals present absolutely the same appearance under the microscope, and differ somewhat from the only other known hydrated lead aluminium phosphate, viz. the plumbogummite from Huelgoat in Brittany. Mr. Hartley's analyses of this mineral differ from those of Damour, and shows that it has by no means the same composition as hitchcockite, and it is therefore considered to be a distinct species.—Mr. H. L. Bowman gave a detailed description of the optical crystallographic and chemical characters of a clear green rhombic pyroxene from the diamond-washings of South Africa.—Messrs. G. T. Prior and L. J. Spencer contributed a paper on the chemical composition of tetrahedrite. In a previous investigation proving the specific identity of the rare mineral binnite with tennantite, the numbers obtained in the analysis, like those of several older analyses of tennantite, agreed much more closely with the formula $3Cu_2S.As_2S_3$ than with the ordinary text-book formula $4Cu_2S.As_2S_3$, originally proposed by Rose. In the present communication the authors describe the physical and chemical characters of three specimens of tetrahedrite. The result of the analyses made by Mr. Prior is to confirm the idea that the true formula for tetrahedrite proper is $3Cu_2S.Sb_2S_3$, and also to show that when iron and zinc are present they enter into the composition of the crystals not as $3(Fe,Zn)S.Sb_2S_3$, but as $6(Fe,Zn)S.Sb_2S_3$, in which $6(Fe,Zn)S$ isomorphously replaces $3Cu_2S$. The proposed general formula for fahlerz (tetrahedrite and tennantite) is accordingly

$$3R'_2S.R'''_2S_3 + x[6R''S.R'''_2S_3]$$

where $R' = Cu, Ag$; $R''' = Sb, As, Bi$; $R'' = Fe, Zn$, and $x$ is generally a small fraction, rising, however, to $\frac{1}{2}$ in the case of the highly ferriferous tetrahedrite "coppite."—Mr. L. Fletcher described the chemical analysis of a constituent of the meteoric iron of Youndegin, Western Australia, and gave an account of the fall of meteoric stones at Mount Zomba, British Central Africa, on January 25, 1899.—Mr. Herbert Smith pointed out the specific identity of the new oxychloride of lead paralaurionite, described by him in April 1898, with the new mineral rafaelite, a description of which by the late Dr. Arzruni has just been published.

**Geological Society**, June 21.—W. Whitaker, F.R.S., President, in the chair.—On a series of agglomerates, ashes, and tuffs in the Carboniferous Limestone series of Congleton Edge, by Walcot Gibson and Dr. Wheelton Hind. With an appendix on the petrography of the igneous rocks, by H. H. Arnold-Bemrose. After referring to the discovery of volcanic rocks in the upper part of the Carboniferous Limestone series at Tissington, the authors proceed to describe evidence of volcanic action of the same age on the western slopes of Congleton Edge.—On some ironstone fossil nodules of the Lias, by E. A. Walford.—Additional notes on the glacial phenomena of Spitsbergen, by E. J. Garwood. This paper contains the results of additional observations on the ice of Spitsbergen made by the writer in 1897. The inland ice visited occupies two distinct areas, separated by Dickson's Bay and Wijde Bay. The radiating point lies somewhat north-west of the centres of each area, with supplementary radiating points on the north and east. The group of peaks including the Three Crowns may be regarded as nunatakkr. The valley-bound ground-ice does not necessarily travel in the same direction as that of the surface. The effect of nunatakkr on the surface of the ice-sheet was studied, and from this it was often found possible to infer the existence and position of buried mountain-ridges. On the *stoss-seite* of a nunatak moraine-material is often discharged. The movement of the ice has frequently converted the ice-bridges across crevasses into arches and tunnels, some of which carry part of the drainage of the ice-sheet. Portions of old stranded ground-moraines, formed when the ice was more extensive, were sometimes found to have fallen upon the lowered ice-sheet, and to be mingled with modern moraine-material. Englacial and superficial rivers are described, and one of the latter was found to be depositing gravelly material along a line at right angles to the valley down which the ice was flowing. Certain observations on the rate of movement of the ice-sheet seem to indicate that this is not less than fifteen to twenty feet in twenty-four hours; while the glaciers near the sea-margin appear to be travelling about twenty-five feet in the same time. The action of sea-ice is described, and it is inferred that a certain amount of rounding and scratching of shore-rocks, and possibly part of the smoothing of boulders, may be due to this agent.—Additional notes on the vertebrate fauna of the rock-fissure at Ightham (Kent), by E. T. Newton, F.R.S.

**Royal Microscopical Society**, June 21.—Mr. E. M. Nelson, President, in the chair.—The President exhibited an old ⅛-inch objective made by Andrew Ross, which had been presented to the Society by the Master of the Rolls. It was a rare form of objective, constructed probably about the year 1838, and possessed a very primitive form of adjustment. A special interest was attached to it because it formerly belonged to the father of the donor, Prof. John Lindley, the second President of the Society (1842–43).—The President also exhibited a new coarse adjustment which Messrs. Watson had made in accordance with a suggestion contained in his paper read before the Society in March last. It showed that with a loose pinion it was possible to have a rack coarse adjustment that would work without "loss of time."—A paper by Mr. Jas. Yate Johnson, entitled "Notes on some sponges belonging to the Clionidæ obtained at Madeira," was taken as read. Six slides of Spiculæ, &c., in illustration of the paper, were exhibited under microscopes.—The President called the attention of the Fellows present to an exhibition by Mr. Beck of parts of various wild flowers shown with low powers.—This was the last meeting of the session, and the President announced that the first meeting after the vacation would be on October 18.

EDINBURGH.

**Royal Society**, June 5.—Sir Arthur Mitchell in the chair.—A note by Dr. Thomas Muir, on a persymmetric eliminant, was taken as read.—Dr. A. T. Masterman read a paper on contributions to the life-histories of the cod and the whiting. The paper was illustrated by numerous diagrams tracing the successive stages of development from lengths of 3 mm. to lengths of 25 mm. There was found to be a greater abundance of pigment in young whiting, and the body shows a characteristic pigmented lateral line. The migration of the young of each species shorewards was also studied. In the case of the cod the transition was very marked from surface to mid-water, and thence to the littoral region. Thus the limiting length of surface forms was 17 mm., of mid-water forms a little over 25 mm., and later forms were all found in the littoral regions. No attempt has as yet been made to trace outward migration, if there be any. As had already been pointed out by Prof. McIntosh, the migration of the whiting was much more indefinite. Sufficient causes for these migrations had not yet been satisfactorily made out.—Dr. Hugh Marshall gave a preliminary note on the hydrolysis of thallic sulphate.

June 19.—Sir William Turner, F.R.S., in the chair.—A paper by Dr. Thomas Muir, on the eliminant of a set of general ternary quadrics, was taken as read.—Messrs. A. C. Seward, F.R.S., and A. W. Hill presented a paper on the structure and affinities of a Lepidodendron stem from the Calciferous Sandstone of Dalmeny. The fossil stem described in this paper was found by Mr. J. Kerr, of Edinburgh, and generously handed over by Mr. Robert Kidston, of Stirling, to Mr. Seward for examination and description. The peripheral portion of the stem is occupied by a band of secondary cortical tissue (phelloderm) about 5-7 cm. in breadth; the more internal cortex has not been preserved, but the central cylinder is unusually perfect. The specimen measures 33 cm. in diameter. A fairly broad pith occupies the centre of the stem, and this is enclosed by a ring of primary xylem succeeded by a broad band of secondary xylem. The leaf traces exhibit a well-marked secondary growth; each consists of a few primary tracheids, accompanied by a fan-shaped group of short and thin-walled tracheal elements. The stem appears to be identical with *Lepidophloios Wunschianus* from Arran, and a comparison is also instituted with *Lepidophloios Harcourtii*, a species characterised by the absence or late development of secondary wood.—Dr. T. H. Bryce read a paper on duplicitas anterior in an early chick embryo. This very rare condition in birds was examined in careful detail, and the structure of the duplex embryo was demonstrated by microphotographs of typical section.—In a paper on the trap-dykes of the Orkneys, Mr. J. S. Flett gave a description of a series of trap-dykes running mostly in an east-north-east direction, and cutting the Old Red Sandstone of Orkney. They are principally camptonites, but include also bostonites, monchiquites, fourchites, alnoites, and mellilite monchiquites. They are remarkably fresh, and show an interesting series of gradations between the different types. They are probably of Tertiary age, and have all proceeded from one focus. The presence of a single diabase dyke points to their origin from a gabbro magma.—Miss E. Chick presented a paper on the vascular system of the hypocotyl and embryo of *Ricinus communis*, which contained a detailed study of the behaviour of the vascular system in its passage from the root to the stem. Certain anomalies which have been observed were explained, and the inquiry brought out very clearly the individuality of the bundles as compared with the whole central cylinder of the root to which they belong.—Dr. W. Peddie, in a note on Mr. J. O. Thompson's paper on torsional oscillations (see NATURE, May 25, p. 86), pointed out that Mr. Thompson's suggested explanation of the results described by Lord Kelvin is very improbable, for there is no apparent reason why too large an initial oscillation should be given always to the fatigued wire and not to the unfatigued wire. Experiments on an iron wire, already described by Dr. Peddie, showed distinct fatigue of elasticity. It was also pointed out that Mr. Thompson's own results seem themselves to indicate fatigue.

PARIS.

**Academy of Sciences**, June 26.—M. Van Tieghem in the chair.—Note accompanying the presentation of the fourth part of the photographic atlas of the moon, by MM. Loewy and Puiseux. The salient characters of the regions represented are described.—Preparation of fluorine, by electrolysis, in an apparatus of copper, by M. Henri Moissan. The costly platinum apparatus hitherto employed in the preparation of fluorine may, it is found, be replaced by one of copper, which is less attacked than most other metals. It is probable that the copper becomes coated with a thin layer of copper fluoride which, being insoluble in hydrofluoric acid, prevents further action taking place.—Action of some gases on caoutchouc, by M. D'Arsonval. At pressures varying from 1 to 5 atmospheres caoutchouc absorbs large quantities of carbonic anhydride and, at the same time, increases considerably in volume and becomes more gelatinous and less elastic. On exposure to air the gas is gradually lost, and the substance resumes its original properties. In virtue of this property, vessels of caoutchouc readily allow car-

bonic anhydride to pass through their walls. The action is much slower in the case of oxygen and is very slight with nitrogen.—The report of the commission recommending the revision of the map of France was adopted.—Observations on the work of MM. S. Lie and A. Meyer. A mathematical paper.—A new formula relating to quadratic residues, by M. P. Pépin. A paper dealing with the theory of numbers.—On the equation of motion of automobiles, by M. A. Petot. A reply to the criticisms of M. Blondel on a former communication by the author.—On the temperature of maximum density of aqueous solutions of alkali chlorides, by M. L. C. De Coppet. Experiments were made with the chlorides of potassium, sodium, lithium, and rubidium. It is remarkable that the molecular lowering of the point of maximum density caused by lithium chloride is less than half that observed in the case of the other salts examined.—On an oscillation phakometer, by M. Ch. Dévé. The superior accuracy claimed for this instrument for measuring the curvature of optical surfaces, &c., depends on the use of a novel artifice for determining the exact position of an image.—On a laboratory spectroscope in which the dispersion and the scale are adjustable, by M. A. De Gramont.—On the polarisation of dielectrics, by M. Liénard. Observations on a previous note by M. Pellat on this subject.—Results of seismic observations in Greece from 1893 to 1898, by M. D. Eginitis. During the six years over which the observations extended 3187 disturbances were recorded, the average annual number being 531 and the maximum 876 (in 1893). Seismic disturbances are more frequent in the night than in the day, and, as regards their annual distribution, exhibit a maximum in spring and a minimum in autumn.—On the constitution of the oxides of rare metals, by MM. G. Wyrouboff and A Verneuil. Considerations relative to the formation of various complex salts of cerium and thorium lead to the suggestion that the oxides of these metals have the formulæ $(CeO)_3$ and $(ThO)_4$ respectively, in which one of the CeO or ThO groups differs in function from the rest.—The action of ferric chloride and bromide on some aromatic hydrocarbons and on their halogen substitution derivatives, by M. V. Thomas. A continuation of previous work on the subject. From the product of the action of ferric chloride on paradibromobenzene the author has succeeded in isolating two new bromotrichlorobenzenes which melt at 93° and 138° respectively.—The preparation of phenylic chlorocarbonates, by MM. Et. Barral and Albert Morel. The action of a solution of carbonyl chloride in toluene on an aqueous solution of the sodium compound of phenols is shown to afford a ready means of preparing a number of aromatic chlorocarbonates. The temperature at which the reaction takes place should not exceed 40–50°, otherwise decomposition ensues, and the symmetrical phenylic carbonate is produced.—On cerine and friedeline, by MM. C. Istrati and A. Ostrogovich. By fractional dissolution in, and crystallisation from, chloroform, the substance formerly described by one of the authors as extracted from cork has been separated into two distinct compounds, cerine, $C_{27}H_{44}O_2$, and friedeline, $C_{43}H_{70}O_2$.—On some new reactions of indolic bases and albuminoid compounds, by M. Julius Gnezda. When indol and its derivatives are heated with excess of oxalic acid, a fine purple coloration is developed, and a similar reaction is given by albumen, peptones, and gelatin. Some other dibasic acids may be used instead of oxalic acid. Other colour reactions brought about by hydrofluoric acid and hydrofluosilicic acid are also described.—Preliminary tests for the presence of rare metals in mineral waters, by M. F. Garrigou. In the author's opinion, the presence of rare metals of the copper and tin groups in mineral waters is more frequent than is generally supposed.—On the formation of pearls in *Meleagrina margaritifera*, by M. Léon Dignet. Genuine pearls are not simple deposits of nacreous material accidentally produced by glandular secretions, but are the result of a definite physiological action having for its aim the elimination of parasites or other causes of irritation.—On the embryogeny of *Protula meilhaci*, by M. Albert Soulier.—Regeneration of members in *Mantides* and the constant production of a tetramerous tarsus in members regenerated after autotomy in pentamerous *Orthoptera*, by M. Edmond Bordage.—On the histology of the digestive tube in the larva of *Chironomus plumosus*, by M. P. Vignon.—Contribution to the study of *Actinidia* (*Dilleniaceae*), by M. Florentin Dunac.—On the experimental production of fascicular stems and inflorescences, by M. L. Géneau de Lamarlière.—Velocity of propagation of nervous oscillations produced by unipolar excitation, by M. Auguste Charpentier.—General and local anæsthesia of motor nerves, by Mlles. I. Ioteyko and M. Stefanowska.—Physiological significance of alcohol in the vegetable kingdom, by M. P. Mazé.—On the action of currents of high frequency in arthritis, by M. Apostoli.—On the influence of electrolytic action in the production of radiographic erythema, by MM. H. Bordier and Salvador.—Further demonstrations of the variations in the amount of iron present in the tissues under the influence of pregnancy, by M. A. Charrin.

GÖTTINGEN.

Royal Society of Sciences.—The *Nachrichten* (physico-mathematical series), part i. for 1899, contains the following memoirs communicated to the Society:—

## SAUNDERS'S BRITISH BIRDS.

*An Illustrated Manual of British Birds.* By Howard Saunders. Second Edition; revised. Pp. xl + 776. Figs. and Maps. (London: Gurney and Jackson, 1897–99.)

THE demand for works on British birds shows no signs of diminution, the popularity of the present instructive volume being vouched for by the fact of the exhaustion of the first edition of 3000 copies in less than eight years from the date of completion. The first edition being out of print early in 1897, the publishers lost no time in preparing a second, which commenced in November of that year and was completed on the first of June last. That this new issue is in no sense a mere *replica* of the preceding one is at once shown by a glance at the preface, where it is stated that, while the number of species admitted as British was then 367, it has now been raised to 384. Of course, these additional species are merely stragglers; and it seems to us that, in cases like those of the frigate-petrel and the black-browed albatross, it would have been decidedly better to include such stragglers in a separate list, as they have nothing whatever to do with the true British fauna. It must, however, be admitted that in making such a list of foreign stragglers it would be exceedingly difficult to know where to draw the line, so that we are not going to blame the author for the course he has thought fit to pursue.

The accounts of the various species, although necessarily somewhat brief, are all that can be desired from a popular point of view; and as these accounts are in nearly all cases supplemented by an excellent illustration, it may be safely said that there is no other work of its size in which so much information on the subject of British birds can be obtained. The great majority of the illustrations are the same as those in the fourth edition of "Yarrell"; and although the impressions of many of these do not compare favourably when contrasted with the latter, yet their attractive character and zoological accuracy may well justify their use. New figures, by Mr. G. E. Lodge, are, however, given of many of the species recently added to the British list, while a considerable number of the old-established birds have been redrawn by the same talented artist. A special feature of the work is the carefully compiled synopsis of genera in the introduction, where all the essential diagnostic characters of each are given in simple and yet precise terms. Another notable feature is afforded by the three admirably coloured maps at the end of the volume. The first of these shows the comparative elevation of the land and the depth of the surrounding seas in the United Kingdom, while the second does the same for Europe generally. The former, as the author states, serves to remind the reader that, owing to the indentations of the coast, comparatively few spots in the British Islands are situated at a distance of more than fifty miles from the coast; and how important a bearing this has on climate—and consequently on bird-life—scarcely needs mention. The third map is a North Polar chart, embodying Nansen's discoveries; and although this is primarily intended to assist in estimating the range of Arctic-breeding species, it will be found highly useful to many others besides ornithologists.

Fortunately, Mr. Eagle Clarke's valuable digest on bird-migration appeared in time for its results to be incorporated in this volume. And how important are these results in regard to the non-continuation of the Heligoland migrations to Britain, and also in respect to the effects of wind on migration, needs no telling on this occasion.

With regard to the difficult subject of classification, we are glad to find that the author follows the lines of the last edition of "Yarrell," so that the number of families and genera is considerably less than in certain other recent manuals of British birds. We are likewise pleased to see the retention of the old ordinal names, such as Passeres and Gallinæ, instead of their fashionable substitutes Passeriformes and Galliformes. So, too, is it refreshing to notice the absence of alliterative names; the familiar goldcrest, for instance, appearing as *Regulus cristatus* instead of *Regulus regulus.*

At the same time, it is greatly to be deplored that ornithologists should not, by a system of give-and-take, come to some general agreement over what is really, in one sense, an extremely unimportant matter—*i.e.* the names and limits of the orders, families, genera, and species of British birds. In the introduction, the author observes that the limits of a genus are mainly—and often purely—a matter of convenience. With this statement we thoroughly agree; but it is surely a matter of the most extreme *inconvenience* when each and every writer on British birds adopts his own views on such limits, without any regard to those of his fellow workers.

Contrast, for instance, Mr. Saunders's classification of the *Turdidae* (Thrush family) with the grouping of the genera contained therein by Mr. Sharpe in his "Handbook of British Birds," as exemplified in the following table:—

| SAUNDERS. | SHARPE. |
|---|---|
| Fam. Turdidæ. | Fam. Regulidæ. |
| Sub-fam. Turdinæ. | 1. *Regulus.* |
| 1. *Turdus.* | Fam. Turdidæ. |
| 2. *Monticola.* | 2. *Oreocichla.* |
| 3. *Saxicola.* | 3. *Geocichla.* |
| 4. *Pratincola.* | 4. *Merula.* |
| 5. *Ruticilla.* | 5. *Turdus.* |
| 6. *Cyanecula.* | 6. *Daulias.* |
| 7. *Erithacus.* | 7. *Erithacus.* |
| 8. *Daulias.* | 8. *Cyanecula.* |
| Sub-fam. Sylviinæ. | 9. *Monticola.* |
| 9. *Sylvia.* | 10. *Ruticilla.* |
| 10. *Regulus.* | 11. *Saxicola.* |
| 11. *Phylloscopus.* | 12. *Pratincola.* |
| 12. *Aedon.* | Fam. Sylviidæ. |
| 13. *Lusciniola.* | 13. *Sylvia.* |
| 14. *Hypolais.* | 14. *Melizophilus.* |
| 15. *Acrocephalus.* | 15. *Aedon.* |
| 16. *Locustella.* | 16. *Phylloscopus.* |
| Sub-fam. Accentorinæ. | 17. *Hypolais.* |
| 17. *Accentor.* | 18. *Acrocephalus.* |
| | 19. *Locustella.* |
| | Fam. Accentoridæ. |
| | 20. *Tharrhaleus.* |
| | 21. *Accentor.* |

Here we have one author making three families out of what the other regards as one, while he expands

sixteen[1] genera of the former into twenty-one. If specific names were taken into consideration, further discrepancies would be noticeable. Moreover, in many of the other families of birds the two authors do not agree in regard to several of the generic names. For example, in the case of the ruff and reeve Mr. Saunders retains the Cuvierian *Machetes*, while Dr. Sharpe employs the earlier *Pavoncella*.

Such differences and idiosyncrasies are irritating enough to the working naturalist who knows what he is about, but to the amateur and the beginner they must be absolutely maddening. Although personally we are inclined to side with Mr. Saunders in regard to the limits of genera, and with Dr. Sharpe in regard to the adoption of the earliest names for the same, we consider both matters of no importance at all in comparison with uniformity of usage. And it is, we think, high time ornithologists settled upon some uniform working basis. Otherwise, we are of opinion the sooner scientific names are given up the better; they were intended for our tools, and we are rapidly making them our masters.

In the last few paragraphs we have departed rather widely from our text; and, to revert to the same, we may conclude by expressing the hope that the second edition of the "Boy's Yarrell," as the work before us has been not inappropriately termed, may meet with as favourable a reception from the public as has been accorded to its predecessor. R. L.

[1] *Lusciniola*, for Radde's bush-warbler, was not known to be British when Dr. Sharpe wrote.

## *AS REGARDS REGENERATION.*

*Thatsachen und Auslegungen in Bezug auf Regeneration.* Von August Weismann. Pp. 31. (Jena: Gustav Fischer, 1899.)

PROF. AUGUST WEISMANN'S essay on regeneration, which appeared simultaneously in *Natural Science* and in the *Anatomischer Anzeiger*, has now been published in pamphlet form, and well deserves the careful consideration of biologists. Its contents may be divided into two parts, the first of which is independent of the second. In the first part, Prof. Weismann expounds his previously expressed conclusion that regeneration is an adaptive phenomenon—"that the regenerative power of a part is to be considered, not as a direct and necessary expression of the nature of the organism, but rather as a capability which, though it may be absent, is found wherever it is necessary in the interests of species-preservation." In other words, the power of regenerating lost parts, though depending primarily (like all other vital qualities) on the properties of organised protoplasm, has been defined and perfected in the course of natural selection in those organisms which are in the ordinary course of their life frequently liable to serious mutilation. This is not a new idea, for, as Weismann notices, Réaumur made, in the first half of the eighteenth century, the induction that the power of regeneration was especially characteristic of animals whose brittle body was frequently liable to risk of breakage, and also of those, like earthworms, which are liable to be partially devoured. The Italian naturalist Lessona gave more precise expression to the same induction in what is sometimes called "Lessona's law," while Darwin regarded the regenerative capacity as interpretable on his theory of the selective origin of adaptations.

But since the days of Lessona and Darwin the wide occurrence of regenerative capacity throughout the animal series, till it fades away to almost nothing in mammals, has been more adequately appreciated, and besides observations not a few experiments have been made, so that the literature of the subject is already enormous Weismann, more perhaps than any other, has the credit of having recognised the importance of the problem presented, and of having tried to face the facts with a theory.

The first part of the pamphlet is an argument in favour of the interpretation of the regenerative power as an adaptive phenomenon. (1) It has been objected that regeneration sometimes occurs where the loss could only be called a casualty, and not such as would occur in the ordinary course of nature, *e.g.* a bird's regeneration of a broken beak, or a newt's regeneration of an eye. But as one inquires further into the matter it becomes probable that these injuries are much more frequent than was imagined, and that they cannot be called casualties. (2) It has been objected that internal organs not naturally exposed to mutilation or periodical wearing out are sometimes regenerated. But there seem to be few cases where this has been really substantiated, though some observations—by Vitzou, for instance, on monkeys—lead us to doubt whether Weismann is quite warranted in saying that regeneration of brain-cells in mammals never occurs. (3) T. H. Morgan's experiments on hermit-crabs showed that all the appendages were capable of regeneration, both those most liable to injury and those naturally well-protected, and led him to the conclusion that there is no relation between the frequency of loss and the regenerative capacity. With this case Weismann deals at considerable length and with his wonted ingenuity, calling to his aid especially the idea that the variation of the regeneration-"anlage" may lag behind the phyletic transformation of the part in question. But is it not enough to say that the fallacy underlying Morgan's objection is that of treating an organism as a finished product, and of assuming that an adaptation must be perfect? (4) It has been objected that regeneration does not occur in many cases where it would be very useful, thus its occurrence among reptiles, as regards the tail, is strangely sporadic, one might be tempted to say capricious. But is not this an *argumentum ad ignorantiam*, is it not likely that as we know more about the actual conditions of life in the apparently puzzling cases, the difficulties will disappear? Moreover, must it not be admitted that the absence of regeneration may be explained by the presence of another life-saving adaptation on totally different lines, and that, after all, adaptations are but compromises, and by no means perfect? Thus it is hardly an argument against the generally adaptive character of regeneration in earthworms to cite a case where the mutilated creature grows a second tail instead of a new head. One might as well say that the quickness of cerebral activity was not an effective adaptation because some people sometimes lose their heads.

But we must not prolong our review of this able essay on these familiar lines. Suffice it to say that to those who enjoy this sort of discussion, and who appreciate its serious significance, this last utterance from the renowned biologist of Freiburg—though somewhat more discursive than is his wont—will afford, as the saying is, both pleasure and profit.

The second part of the essay contains an attempt to show, not merely that regenerative phenomena are adaptive, and presumably the outcome of selection, but that they are interpretable, on the ontogenetic theory of "anlagen," "determinants," "neben-Determinanten," "reserve germ-plasm," and the like. This is quite another affair, and altogether too complex to be dealt with in a few lines. But we would venture to insist that the evolutionary or phylogenetic interpretation of regeneration phenomena as adaptive is independent of the subtler developmental or ontogenetic theory of the manner in which the capacity may be supposed to organise and express itself.

It seems to us regrettable that Prof. Weismann should condescend to notice the "invectives, sarcasm, and derision which have been showered upon" him, and that he should regard

"Such utterances as a not exactly desired, but yet not altogether unsatisfactory, sign that the less noble emotions of human nature—envy and ill-will—have found cause to direct themselves against the results of my work."

No doubt criticism without knowledge is exasperating, but it is also humbug; no doubt invective without appreciation is irritating, but it is mere pettifogging; and why should the immortals concern themselves about either?

A more philosophical temper, which we should regard as more deeply habitual, is indicated in one of the paragraphs towards the end of the pamphlet.

"One of my critics has compared my 'theories' to 'towns in the Far West,' the houses of which are barely erected when they are taken down again to be rebuilt further out in the unknown land. I accept the simile, provided it be not forgotten that the first house of the advancing pioneer must remain standing and in use for a time before the region beyond becomes accessible to further colonisation."

We would respectfully commend to the illustrious author a motto from a northern University, "They have said, What say they? Let them say." For the author of the "Germplasm" and "Germinal Selection" is surely, among living biologists, the foremost pioneer. J. A. T.

## WEST AFRICAN FETISH.

*West African Studies.* By Mary H. Kingsley. With illustrations and maps. Pp. xxiv + 639. (London: Macmillan and Co., 1899.)

FOR the last three years Miss Kingsley has been known to the scientific world as a careful collector of facts relating to West Africa, while to the unscientific public interested in works of exploration and travel she is known as a writer with an original and very entertaining manner. Her book entitled "Travels in West Africa," which was published in 1896, was the result of two journeys to West Africa, where she had devoted herself to the study of fetish and fresh-water fishes. In the preface to her present volume she tells us that her previous work, which she rather unjustly refers to as "a word-swamp of a book," was of the nature of an interim report. She there confined herself to facts, and eliminated as far as possible any inferences that might be drawn from them, distrusting at the time her own ability to make theories, and intending that ethnologists should draw from her collections of material such facts as they might care to select. The use that has been made of the volume since its appearance has certainly justified Miss Kingsley's method of publication. But there was obviously room for another work on the same subject from her pen. No one was better qualified than herself to form opinions with regard to the beliefs and practices she studied, and we are glad to find that in the present work she has formulated the conclusions at which she has arrived. We welcome the book as a valuable supplement to the first volume of her travels.

The book contains a good deal or very varied information, and while some portions of it appeal to the anthropologist and student of religion, others deal with purely scientific observations, and others again are of a political nature. Miss Kingsley's criticism of the Crown Colony system will doubtless receive the attention it deserves at the hands of those who are responsible for the methods we adopt as a nation in dealing with our tropical possessions. Her chapter entitled "Fishing in West Africa," which has already appeared in the *National Review*, explains the means by which she was enabled to form the collections which won Dr. Günther's admiration; while in the same connection we have an interesting account of the little fishes (*Alestis Kingsleyae*) which have the honour to bear their discoverer's name. The most interesting part of the book, however, which Miss Kingsley herself regards as of greatest importance, is the section which deals with the subject of fetish in West Africa. The word fetish is used by Miss Kingsley in a much wider sense than that in which it is generally employed at the present day. The word was adopted into scientific literature from the writings of the old Portuguese navigators, who were the modern discoverers of West Africa. These men noticed the veneration paid by Africans to inanimate objects, and called these things *Feitiço*, a term they applied to their own talismans and charms. The word is nowadays generally employed in a rather similar sense as a general term for the doctrine of spirits embodied in, or conveying influence through, material objects. Miss Kingsley, however, in spite of a protest from Prof. Tylor, has thrown over this established usage, and employs the word as a convenient synonym for the religion of the natives of the West Coast of Africa where they have not been influenced either by Christianity or Mohammedanism. Using the term with this extended application, Miss Kingsley classifies West African fetish into four main schools: the Tshi and Ewe school, which is mainly concerned with the preservation of life; the Calabar school, which attempts to enable the soul to pass successfully through death; the Mpongwe school, which aims at the attainment of material prosperity; and the school of Nkissi, which chiefly concerns itself with the worship of the power of the earth. These schools of fetish are not sharply defined, and many of the same

things are worshipped indiscriminately in each; but Miss Kingsley has shown that in certain schools certain ideas are predominant, and her classification is based on a general survey which can afford to ignore minor inconsistencies. It is interesting to note that, according to Miss Kingsley's observations, the African, to whatever school of fetish he may belong, conceives of a great over-God, who has below him lesser spirits including man. But this fact does not necessarily support Mr. Andrew Lang's recently promulgated theory as to the original purity and elevation of the religious beliefs of primitive races, though Miss Kingsley herself is inclined to identify her own conception of things with that she found current among the peoples she studied. We have merely touched on the principal sections of Miss Kingsley's very interesting work, and have not space to do more than recommend its perusal to all those interested in the religions of the undeveloped races of mankind. The reader will find in it much material of the greatest scientific importance, while its anecdotes and lively style render it one of the most entertaining books of travel and observation that has appeared for many years.

## *OUR BOOK SHELF.*

*Catalogue of the Library of the Royal Botanic Gardens, Kew.* (London, 1899.)

THE issue of this catalogue fittingly commemorates the development, up to the last year of the nineteenth century, of an adjunct indispensable in the equipment of a centre of botanical research so deservedly famous as the Royal Botanic Gardens at Kew. The many botanists that have enjoyed the access to the library so freely allowed to workers in the Herbarium, and have learned to value the stores of information contained in it, will rejoice to have the catalogue as a guide to render the riches of the library still more accessible than in the past. But not to those alone that can visit Kew Herbarium is it likely to be welcome. Botanists living at a distance that precludes frequent visits to Kew Herbarium will find it most useful for reference as a guide to the literature of botany, and will value it accordingly.

The size of the library may be judged from the fact that a rough calculation shows upwards of 15,000 separate entries of books or papers, besides numerous cross-references. Of course, all sides of botanical research are represented, from the more elementary to the most profound, from the most rigid study of botany as pure science to its practical applications to industries and arts, to folk-lore, and to its manifold links with other fields of study, scientific and literary. Occasionally one meets with a title that at the first glance seems to have little connection with botany, *e.g.* W. Ridgeway's "The Origin of Metallic Currency and Weight Standards," yet these only serve to show the curious relations of botany to other studies.

The entries are divided into four series, each arranged alphabetically:—(1) General, occupying 683 pages; (2) Travels, 43 pages; (3) Periodicals and Serials, 47 pages; (4) Manuscripts, 15 pages, large octavo.

The catalogue has been prepared by Mr. B. Daydon Jackson, and is marked by the accuracy so characteristic of all his work in botanical bibliography. Despite the peculiar risk of errors in transcribing and printing the titles and necessary details, many of which are in very unfamiliar languages, the freedom from errors is very noteworthy.

An introduction to the volume from the pen of the Director of the Gardens gives a brief account of the leading facts in the formation of the library, which originated as a public library in 1852, when Miss Bromfield presented to the Gardens the botanical books that had belonged to her deceased brother, Dr. W. A. Bromfield. Sir William Hooker, on his appointment as Director in 1841, had offered to make his large private library and herbarium available for public use if they were suitably accommodated. This was done in a house provided for him as Director until 1852, when they were transferred to the present Herbarium, though still remaining his private property. In 1854 the late George Bentham, F.R.S., very generously gave his large botanical library to the Herbarium, where in subsequent years he long continued those researches by which he so greatly advanced the science of botany. In 1867, after Sir William Hooker's death, the Treasury sanctioned the purchase for the library of those botanical works that had belonged to him and that the library did not possess.

Valuable legacies and gifts have also been received from other sources, and numerous serials are obtained in exchange; and purchases are made with occasional grants from the Bentham Trust. The sum expended from public funds in the formation of the library has been very small in comparison with its value, and has consisted of a small annual subsidy since 1849, supplemented after some years by free binding by the Stationery Office. One important source of constant additions—the gifts of books and separate papers from the authors—is largely the result of the benefits experienced by the botanists that come from far and near to pursue researches at Kew.

The catalogue would become still more valuable to botanists if there could be added a subject-division, even under large sections, of the multitude of titles that it contains. The difficulties of doing so are indeed considerable, but the aid to workers would be very great.

*The Larvae Collector's Guide and Calendar.* By J. and W. Davis. Pp. 90. (Dartford: J. and W. Davis.)

THE times of the appearances of the British macrolepidoptera are given in this little book, together with notes on rearing lepidoptera from eggs, larvæ, and pupæ. Young naturalists should find the volume useful in stocking their butterfly cages, and as a guide to the management of insects in the different stages of development.

## *LETTERS TO THE EDITOR.*

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

### A Lecture Experiment on the Relative Thermal Conductivities of Various Metals.

MOST lecture experiments on the conductivities of metals occupy too much time to be very effective, and in addition are often somewhat uncertain in their action. The following arrangement may be very quickly and simply put together, and by its aid the relative conductivities of a number of metals may be quantitatively determined in an interval of about a minute, the essential parts of the apparatus being capable of projection on a screen.

A piece of brass tube, about 10 cm. in diameter and 20 cm. in length, is closed at one end by means of a brass disc. A number of holes are bored in this disc to receive the extremities of rods of copper, brass, iron, &c., each rod being 2·5 mm. in diameter and about 15 to 20 cm. in length. The rods are soldered in position perpendicular to the disc.

Each rod is provided with a small index, made from a piece of copper wire of about ·8 mm. diameter, bent into the form shown in Fig. 1, a small arrow-head of blackened paper or mica being attached by shellac varnish. The rings forming part of each index are wound on a rod *very slightly* larger in diameter than the experimental rods.

To start with, the brass vessel is inverted, an index is slipped

on each rod, the single ring (Fig. 1) being left in contact with the disc, and a very small amount of paraffin wax is melted round the rings. When the vessel is supported with the rods downwards, as in Fig. 2, the solid wax holds the indexes in position. The arrangement is then placed between the condenser and the focussing lens of the lantern, and boiling water is poured into the brass vessel. When that part of a metal rod, in the neighbourhood of the double ring of the index, reaches the

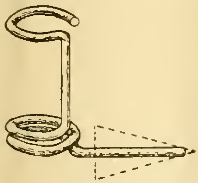

FIG. 1.—Enlarged view of index.

melting temperature of the wax, the index commences to slip downwards, carrying the wax with it, and when the temperatures of the rods have acquired steady values, the indexes will have descended to points on the various rods where the wax just solidifies, and which, therefore, possess equal temperatures. Hence, the conductivities of the various rods are proportional to the squares of the distances from the bottom of the brass vessel to the respective positions indicated by the several arrow-heads.

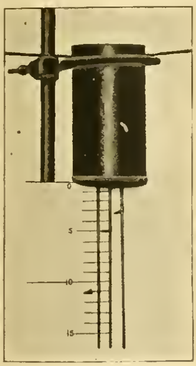

FIG. 2.—Lecture apparatus for demonstrating the relative thermal conductivities of metals. (The left-hand rod is of copper, the middle one of brass, and the right-hand one of soft steel.)

A scale of equal parts, or, better still, a scale of squares, may be drawn on the screen, when the relative conductivities may be directly read off.

In Fig. 2, rods of copper, brass and soft steel are shown with the indexes in the positions acquired at the end of an experiment. It will be seen that the relative conductivities work out to within three or four per cent. of the accepted values for the mean conductivities between 0° and 100° C.

Royal College of Science, July 8. EDWIN EDSER.

## The Electrical Resistance of the Blood.

IT is no easy task to measure the electrical resistance of the blood of a living individual. The principal difficulty depends upon the fact that only very small quantities of blood can generally be obtained at a time. During the last five years many attempts have been made by me to obtain trustworthy and consistent results; various methods and forms of apparatus have been employed and subsequently rejected.

The best results were obtained by placing five cubic millimetres of freshly-drawn blood between two cup-shaped electrodes three millimetres in diameter, coated with spongy platinum, and fixed at 0·75 mm. apart.

The average resistance of normal blood at 60° F. measured by Kohlrausch's method in this apparatus is 550 ohms. A striking change may be observed in pernicious anæmia, the resistance in this disease being sometimes diminished to about one-half that of normal blood. The deduction is that the blood in pernicious anæmia contains an abnormal amount of salts, due to the destructive metabolism going on.

DAWSON TURNER.

## School Laboratory Plans.

I HAVE long believed that by far the best arrangements of the benches in a laboratory for elementary chemical teaching is the last one suggested by Mr. Richardson, viz. "single benches, cross-ways, like the desks of an ordinary class room."

It must be remembered that qualitative analysis now occupies a secondary place in an elementary course, and a great number of reagents is not required for preparations and simple quantitative experiments. The superstructure of shelving may therefore be replaced by a single rack for the common reagents. This allows perfect supervision from the raised demonstration table in front of the benches, and the work of the class can at any moment be interrupted for explanation or revision of the work done, or for an experiment made by the master himself. It is surely a mistake to divide an elementary course of chemistry into two parts—theoretical and practical; the proposed arrangement allows of the practical work forming a part of the general course.

In this county this arrangement has been successfully carried out. The grammar schools are, however, unwilling to risk the refusal of the Science and Art Department to recognise such a laboratory for earning grants, the old-fashioned benches with uncleanly teak tops and rarely used drawers and cupboards being usually insisted on. T. S. DYMOND.

County Technical Laboratories, Chelmsford.

## The Origin of the Doctrine of Compensation of Errors in the Infinitesimal Calculus.

I SHOULD be much obliged if you could help me by inserting a query on this point.

Lazare Carnot, at the end of his "Reflexions sur la Métaphysique du Calcul Infinitésimal," stated that "it is singular that in this indispensable condition of elimination the real character of Infinitesimal Quantities . . . should not hitherto have been discovered."

However, Lagrange (see "Œuvres," t. vii. p. 595) had explicitly stated this doctrine many years before. Very possibly Carnot did not see this note, but Lagrange again stated it in the preface of his "Théorie des Fonctions Analytiques," which Carnot had certainly seen, as he quoted some passages from it in the later editions, at least, of his "Reflexions."

If Carnot has any right to an independent discovery, he could hardly have quoted Lagrange in the first edition of his work. The first edition of both Carnot's and Lagrange's works was dated 1797.

I have been unable to find a first edition of "Carnot" here, so write to ask if any one can tell me whether there is any mention or quotation of Lagrange in it. PHILIP E. B. JOURDAIN.

63 Chesterton Road, Cambridge, June 30.

## Robert Browning and Meteorology.

ROBERT BROWNING'S well-known description of Aurora Borealis, in "Easter Day" (c. xv. xvii), is so graphic that it must have been written from personal observation. Probably few persons can fully appreciate its accuracy; but on September 24, in that wonderful Aurora year 1870, just such a display took place, which I had the fortunate opportunity of watching nearly all night from the Welsh hills, when all the phenomena Browning describes, and many others, were abundantly visible. But I can find no account of any such display having been seen in these latitudes earlier in the century, and "Easter Day" dates from 1850.

The lunar rainbow in "Christmas Eve" (c. iv. and vi.), which "rose at the base with its seven proper colours chorded,"

blending at the summit "in a triumph of whitest white," with a second bow above it, and "a wondrous sequence" beyond that, is evidently the hybrid offspring of fancy and that inaccurate observation of phenomena which seems inevitable without scientific training, especially as, while evening service is going on in Zion Chapel, the moon's "full face" is shining in the West, and the bow appears in "the *empty* other half of the sky," "North and South and East." The effect of "the flying moon" trying to break out of its "ramparted cloud prison" is, however, very graphically described.

But I should like to know when and where the poet could have seen his Aurora. B. W. S.

July 8.

### A Plague of Frogs.

THIS afternoon, as I was walking into Lickey Village from King's Norton, I came across innumerable frogs. They lined the hedges and covered the road so thickly that I had to walk on tiptoe. I thus proceeded quite 400 yards, where the phenomenon ended as sharply defined as it had begun. Nowhere else along the road was a frog to be seen. I was particularly astonished, as I knew the nearest water to be the Little Reservoir—quite $\frac{1}{2}$ mile away. The frogs were about ten days old, very small. A cottage stood about 300 yards from the beginning of this swarm. Upon inquiry I ascertained that the frogs had thus congregated since noon on Monday, that they had literally besieged the house, jumping all over the ground-floor rooms, that the garden and its paths were full of them. The present occupants had lived there $4\frac{1}{2}$ years, but had never experienced anything like this. They have sometimes seen a few frogs cross the road in wet weather. They are now occupied with brushing them out of doors. Can any of your readers explain the cause of this extraordinary spectacle?

King's Norton, Birmingham, July 5. F. H. FORTEY.

## *THE UNIVERSITY OF LONDON.*

AS we went to press last week, an adjourned meeting of the Senate of the University of London was being held to discuss the report of the special committee appointed to consider the offer of the Government to house the University in the Imperial Institute. The history of the negotiations that have taken place may be read in the abridged report published in last week's NATURE; and the facts contained in that statement formed the basis of the discussion in the Senate. In the end the offer of the Government was accepted, the following resolution, proposed by Sir Edward Fry and seconded by Mr. Bryce, being carried by a large majority:

"That the Senate accepts the proposal of Her Majesty's Government as far as it provides in the buildings of the Imperial Institute accommodation for the work hitherto done by the University; and authorises the Committee consisting of the Chancellor, the Vice-Chancellor, and Sir J. G. Fitch to settle the formal terms of agreement with the Government, and the Senate reserves the right of the University to hereafter request the Government to make further provision for such further needs as may arise in the future."

By this resolution the question of the future headquarters of the University is practically settled. The schemes of organisation of the constituent Colleges of the University and future possible teaching centres are now matters of the highest importance, for by them the future work and influence of the University will be determined. An ideal University should encourage the advancement of every branch of knowledge which assists human progress, and it can only do this by admitting into its constitution all subjects with which men of "light and leading" are concerned. It can hardly be held that the University of London has satisfied these conditions in the past, but under the new constitution we may confidently hope that a wider view will be taken of its functions and responsibilities. We have no longer to deal merely with a body authorised to confer degrees by examination, but with a living organisation taking part in the actual work of instruction. The teachers in this great University will feel that the interests of the University are their own interests, and that their work is not to have for its end the preparation of candidates for degrees, but to encourage students to work for the dignity and influence of their *alma mater*.

There are several directions in which the work of the University ought to be developed. Law and medicine should, of course, have their Faculties, as they have in the Universities of Paris, Bologna and elsewhere; and we may surely look to those institutions which have for centuries kept the lamp burning in the absence of a University for the needed heip. Higher commercial education can be provided for by the establishment of a School of Economics and Political Science organised at the Imperial Institute itself. The exceptional facilities offered by the Institute for the work of a school of this character were referred to in an article in NATURE of April 20 in the following words:

"The well-arranged collections of Indian and Colonial products, which form a most important part of the equipment of the Imperial Institute, would be found of especial value in illustrating the teaching of that branch of commercial education known as *Waarenkunde*. Nowhere else in London do similar facilities exist for instruction in the technology of commercial products. Within the building, too, has been provided a chemical laboratory, which is now largely used for the examination and analysis of foreign products; and much of the scientific investigation therein carried on, under the able direction of Prof. Dunstan, is an essential feature in the programme of a high school of commerce. Indeed, a large part of the work which entered into the original scheme of the promoters of the Imperial Institute might, it would seem, consistently, and with great advantage to the public, be continued in that Institute under the auspices of a school of economics, industry and commerce, in connection with the reconstituted University of London. Whether such an arrangement can be effected is a matter for careful consideration; but there is no doubt that the association with the new University of a school of 'economics and political science,' under a separate Faculty, suggests a reasonable basis of union between the educational side of the Imperial Institute and the future University of London."

In connection with this suggestion, another point well deserves consideration. The support which the Colonies have given to the Institute has been in some cases withdrawn on the ground that no advantage was derived from it. But with a commercial school at the Institute colonial students could come over to pursue their studies in the midst of collections illustrating the products of their homes, and the training they would receive with such an environment would ultimately be used for the benefit of the Colonies, so that an adequate return would be made for whatever support was given. In fact, it seems that the use of the collections for the purposes of instruction in connection with the new University would satisfactorily settle the question of the service of the Institute to the Colonies, as well as give colonial students an opportunity of obtaining a degree under the very best conditions.

If the example is once set by using the Institute collections to illustrate courses of instruction on colonial products and industries, it is to be hoped that the other special collections which abound in London illustrating many other branches of culture may also be utilised for University purposes. With its new resources and facilities for advanced teaching, the University is given the opportunity of widely increasing its sphere of influence; and friends of education and national progress look to it to make the best use of the opportunities which the new headquarters will afford.

## THE LIFE OF A STAR.

### A LETTER FROM PROF. PERRY TO SIR NORMAN LOCKYER.

YOU have asked me to examine certain publications on this subject, and to give you my views on the value of such speculations as have been made by mathematical physicists.

Mr. T. J. J. See (*The Astronomical Journal*, Boston, February 6, 1899) states as "one of the most fundamental of all the laws of nature" that gaseous masses follow the law

$$t = \frac{K}{R}$$

where K is a constant for all stars of whatever mass or of whatever kind of gaseous stuff, R is the radius and $t$ is the temperature. Now we have all sorts of temperatures in a star; but whether Mr. See takes average temperature or the temperature of some layer at a definite depth below the surface, he is certainly wrong. Mr. Homer Lane does not express the general results which I shall give presently, nor does Lord Kelvin give them in my form (although he does give them); but from either of these classical papers Mr. See might have inferred them, and seen that his own statement was wrong. Mr. See's arguments are really metaphysical. For example, at the very beginning of the proof of his proposition he speaks of the gravitational pressure at the surface of a star, whereas in physics we do not admit that there can be such a pressure in the absence of outside matter. Thus it is impossible for a mathematical physicist to get to Mr. See's point of view.

Of A. Ritter's articles in *Wiedemann's Annalen* there is a good abstract in the *Astrophysical Journal*, Chicago, December 1898. He assumes that the radiating layer on the outside of a star is of constant mass. He also assumes that the rate of radiation is proportional to the fourth power of the average temperature of this layer. He is dealing with temperatures which are so much greater than the temperatures with which we work in the laboratory, that such assumptions must be regarded as quite arbitrary.

Mr. Homer Lane, in his classical paper on the theoretical temperature of the sun (*American Journal of Science and Arts*, second series, vol. l. p. 57, 1870), makes the assumption that Dulong and Petit's law of radiation is true for solar radiation, and he uses it to calculate the temperature of the radiating layer, which he finds to be 28,000° F. That is, he uses an empirical law, obeyed possibly at laboratory temperatures in radiation from hot solids, to express the radiation at enormous temperatures from a hot layer of gas which has layers of gas of all sorts of temperatures above and below it.

It seems to me that we know too little about the phenomenon of radiation from layers of gas with denser and hotter layers below and rarer and colder layers above to allow of any weight being placed upon these assumptions of Ritter or Homer Lane. In a star we have layers of fluid at all sorts of temperature and density. We have no laboratory knowledge of radiation that is applicable. We know very little about any star except our own sun. During Palæozoic time, many millions of years, there has been life on our earth. Prof. Newcomb is of opinion that the sun's heat received by the earth cannot have varied more than a very little during Palæozoic time. My results will enable us to see what this uniformitarian assumption leads to. It is my own belief (see NATURE, p. 582, April 1895) that there may have been many millions of years during which the sun may have been radiating at only one-third or one-tenth of its present rate. My formulæ will enable us to apply such assumptions as these, and see what they lead to. However different assumptions of this kind may appear to be, they all lead to results which only differ in degree, and not in kind. Assumptions like those of Homer Lane and Ritter may lead to results which are altogether wrong.

All this is speculation, but it is speculation on physical and mathematical lines where criticism is immediately applicable to one's logic and one's premises.

#### *Gaseous Stars.*

Homer Lane, Lord Kelvin, Ritter, and all people who have tried to make exact calculations, have assumed that the stuff of which a star is composed behaves as a perfect gas in a state of convective equilibrium. I also assume that this is the case. But if we apply our results to our own sun, we find that at its centre there is a density 33, that is, 50 per cent. greater than the ordinary density of platinum. It seems to me that speculation on this basis of perfectly gaseous stuff ought to cease when the density of the gas at the centre of the star approaches 0·1 or one-tenth of the density of ordinary water in the laboratory.

Let $\rho$ be density, $t$ absolute temperature, $p$ pressure of the gas at the distance $r$ from the centre; the gas is such that $\rho\sigma t = p$, $\sigma$ being a constant depending on the nature of the gas, and let $\gamma$ be the ratio of its specific heats. Let there be convective equilibrium, so that

$$\rho t^{1/(1-\gamma)} = c_1, \text{ a constant} \quad \ldots\ldots (1)$$

or

$$p t^{\gamma/(1-\gamma)} = c_3, \text{ a constant} \quad \ldots\ldots (2)$$

Let $t_0$ and $\rho_0$ be values at the centre of the star.

If $m$ is the mass inside the radius $r$, then

$$\frac{dp}{dr} = -a\frac{m}{r^2}\rho \quad \ldots\ldots\ldots\ldots (3)$$

[I introduce the constant $a$ because $\frac{m\rho}{r^2}$ is the gravitational force with which a mass $m$ attracts a mass $\rho$ at the distance $r$. If we keep $a = 1$, all our forces will be in gravitational units. I prefer to have them in laboratory units. If we keep to C.G.S. units throughout, as one dyne is the weight of one gramme at the earth's surface $\div 981$ and the weight of one gramme corresponds to $\frac{M_1}{R_1^2}$ gravitation units, where $M_1$ is the mass of the earth in grammes and $R_1$ is the radius of the earth in centimetres; one dyne corresponds to $\frac{M_1}{981\ R_1^2}$ gravitation units, so that

$$a = \frac{981\ R_1^2}{M_1}\Big].$$

Also

$$m = 4\pi\int_0^r r^2\rho\ .\ dr \quad \ldots\ldots\ldots (4)$$

(3) is the same as

$$r^2\frac{c_3}{c_1}\frac{\gamma}{\gamma-1}\frac{dt}{dr} = -am \quad \ldots\ldots\ldots (5)$$

From (4),

$$\frac{dm}{dr} = 4\pi r^2\rho = 4\pi r^2 c_1 t^{\frac{1}{\gamma-1}}.$$

Hence, differentiating (5), we have

$$\frac{d^2t}{dr^2} + \frac{2}{r}\frac{dt}{dr} + \frac{4\pi a(\gamma-1)\rho_0 t^{1/(\gamma-1)}}{\sigma\gamma\ \ t_0^{1/(\gamma-1)}} = 0 \quad \ldots\ldots (6)$$

Let us assume that $t = t_0\theta$, and that $r = bx$, choosing $b$ so that $x$ and $\theta$ shall not depend upon $t_0$ or $\rho_0$, and that the coefficient of the last term is 1, thus we find

$$\frac{d^2\theta}{dx^2} + \frac{2}{x}\frac{d\theta}{dx} + \theta^{1/(\gamma-1)} = 0 \quad \ldots\ldots (7)$$

an equation which is true for any star the $\gamma$ for whose gaseous stuff is known.

$\theta$ which is $t/t_0$ may be expressed as a sum of powers of

$x$, and so tabulated. In the same way, $\phi$ or $\rho/\rho_0$ might be tabulated. Indeed $\phi^{\gamma-1}=\theta$. Again $\mu$ or $\int_0^x \phi x^2 . dx$ may be tabulated. Mr. Lane has done this work for several values of $\gamma$. Solution by means of series of powers of $x$ can be relied upon only till $x=1$. After that one must work indirectly. Lord Kelvin, in a paper published in the *Philosophical Magazine*, 1887, vol. xxiii. p. 287, gives numbers calculated by his assistant, Mr. Magnus Maclean, from which, with the help of Mr. J. Lister's or Mr. Homer Lane's values at $x=1$, I could give a table like the following for the case of $\gamma=1{\cdot}4$. There are outside limits for $x$ and $\mu$, which Mr. Lane calls $x'$ and $\mu'$. Knowing the value of $\theta$ for $x=1$, I find that Lord Kelvin's numbers give $x'$ as 5·24, and the corresponding $\mu'$ as 2·165, whereas Mr. Lane gives $x'$ as 5·35, and $\mu'$ as 2·188. Mr. Lane does not publish the other values, and his curves are drawn to too small a scale for us to be able to make out tables of the values of $\theta$ or $\phi$. Lord Kelvin from $x=0$, and Mr. Lane for values beyond $x=1$, obtained their results by methods such that errors may have increased as the work proceeded.

On the whole, I am disposed to take Lord Kelvin's numbers with an $x'$, which is the mean of those just given, or 5·30, and $\mu'$ as 2·177.

TABLE I.—*For Gaseous Stuff whose Specific Heat Ratio is* 1·4.

| $x$ | $\theta$ | $\phi$ | $\mu$ |
|---|---|---|---|
| 0 | 1·000 | 1·000 | 0 |
| ·795 | ·904 | ·777 | ·136 |
| ·883 | ·884 | ·734 | ·184 |
| ·993 | ·857 | ·679 | ·252 |
| 1·14 | ·819 | ·607 | ·355 |
| 1·33 | ·763 | ·508 | ·512 |
| 1·59 | ·681 | ·385 | ·758 |
| 1·99 | ·562 | ·237 | 1·133 |
| 2·65 | ·384 | ·0916 | 1·666 |
| 3·97 | ·141 | ·0074 | 2·117 |
| 5·30 | 0 | 0 | 2·177 |

We know now that for any star whose stuff behaves like a perfect gas

$$\left.\begin{array}{l} r=\mathrm{A}\left(\dfrac{t_0}{\rho_0}\right)^{1/2}x,\ m=\mathrm{B}t_0^{3/2}\rho_0^{-1/2}\mu \\ t=t_0\theta,\ \rho=\rho_0\phi \end{array}\right\} \quad . \ . \ . \ . \ . \ (8)$$

Where

$$\mathrm{A}=\sqrt{\frac{\sigma\gamma}{4\pi a(\gamma-1)}},\ \text{and}\ \mathrm{B}=4\pi\mathrm{A}^3.$$

we see that A and B, $x'$ and $\mu'$ depend merely on the nature of the gas. We have

$$\mathrm{R}=\mathrm{A}\left(\frac{t_0}{\rho_0}\right)^{\frac{1}{2}}x' \quad . \ . \ . \ . \ . \ . \ . \ . \ (9)$$

$$\mathrm{M}=\mathrm{B}t_0^{3/2}\rho_0^{-\frac{1}{2}}\mu' \quad . \ . \ . \ . \ . \ . \ . \ . \ (10)$$

if R is the outside radius and M is the whole mass.

We may choose values of $t_0$ and $\rho_0$, and calculate R and M, or it is easy to see that if we know R and M, we may calculate the internal density and temperature by

$$\left.\begin{array}{l} t_0=\dfrac{x'}{4\pi\mathrm{A}^2\mu'}\cdot\dfrac{\mathrm{M}}{\mathrm{R}} \\ \rho_0=\dfrac{x'^3}{4\pi\mu'}\,\dfrac{\mathrm{M}}{\mathrm{R}^3} \end{array}\right\} \quad . \ . \ . \ . \ . \ . \ . \ (11)$$

It will be noticed that, $\sigma$ being proportional to the molecular volume (being sixteen times as great in hydrogen as in oxygen), $\rho_0$ is independent of $\sigma$, whereas $t_0$ is inversely proportional to $\sigma$. If we consider our own sun to be made of hydrogen, and if the laws of perfect gases could be applied as we have applied them, $t_0 = 3{\cdot}25 \times 10^7$ degrees centigrade, $\rho_0 = 33$, that is, 50 per cent. greater than the density of platinum (see how I blush). Whereas if it were made of oxygen, $\rho_0$ is the same as before, but $t_0$ is $2{\cdot}03 \times 10^6$ degrees. It is sometimes good to employ, instead of (8)

$$\left.\begin{array}{l} r=\dfrac{\mathrm{R}}{x'}x,\ m=\dfrac{\mathrm{M}}{\mu'}\mu \\ t=\dfrac{\mathrm{M}x'}{4\pi\mathrm{A}^2\mathrm{R}\mu'}\theta,\ \ \rho=\dfrac{\mathrm{M}x'^3}{4\pi\mathrm{R}^3\mu'}\phi \end{array}\right\} \quad . \ . \ . \ . \ . \ (12)$$

The above tables and these formulæ enable us to find the temperature and density at any point in any gaseous star of any mass, size and material (if $\gamma$ is 1·4). The curve connecting $\theta$ and $x$ is the $t$, $r$ curve for any star; the curve connecting $\phi$ and $x$ is the $\rho$, $r$ curve for any star; the scales of measurement are given in (12).

The *intrinsic energy* (not including any gravitational energy) of the whole mass being $h$, since the intrinsic energy of unit mass at temperature $t$ is $kt$, if $k$ is the specific heat (in ergs) at constant volume, and $t$ is $t_0\,\rho_0^{1-\gamma}\,\rho^{\gamma-1}$,

$$h=4\pi k t_0\rho_0^{1-\gamma}\int_0^{\mathrm{R}} r^2\rho^{\gamma}\,.\,dr$$

or

$$h=4\pi k\mathrm{A}^3 t_0^{5/2}\rho_0^{-\frac{1}{2}}\mathrm{X}$$

if X stands for

$$\int_0^{x'} x^2\theta^{\gamma/(\gamma-1)}dx$$

a known number depending only on the value of $\gamma$. Hence

$$h=\frac{k\mathrm{X}x'}{4\pi\mathrm{A}^2\mu'^2}\cdot\frac{\mathrm{M}^2}{\mathrm{R}} \quad . \ . \ . \ . \ . \ . \ . \ . \ (13)$$

If W is the *work done by gravitation* in bringing all the stuff into its present position from an infinite distance,

$$\mathrm{W}=a4\pi\int_0^{\mathrm{R}}\rho m r\,.\,dr=a\mathrm{Y}\frac{x'}{\mu'^2}\cdot\frac{\mathrm{M}^2}{\mathrm{R}} \quad . \ . \ . \ (14)$$

where

$$\mathrm{Y}=\int_0^{x'}x\mu\phi\,.\,dx$$

a known number depending only on the value of $\gamma$.

We can now speculate on these results. If the pieces of stuff which come together to form the nebula are not mere molecules, but of the size of meteors such as reach our earth, W will not be much less than what is here stated. Indeed, we may say that even when a star ceases to be gaseous, and throughout its whole history the value of W is so nearly what is given in (14), that (14) may be used generally in such speculations as these.

A gaseous star doubles all its temperatures and its intrinsic heat energy when its radius is halved. We see that if all stars are of the same gaseous stuff, the ratio of $h$ to W is constant for all stars at all times. Let us put $\mathrm{W} = a\,\dfrac{\mathrm{M}^2}{\mathrm{R}}$, $h = \beta\,\dfrac{\mathrm{M}^2}{\mathrm{R}}$

As $\mathrm{W} = h + \mathrm{H}$ if H is the total energy lost by the star by radiation, then

$$\mathrm{H}=(a-\beta)\frac{\mathrm{M}^2}{\mathrm{R}} \quad . \ . \ . \ . \ . \ . \ . \ . \ (15)$$

As part of this heat was lost by the stuff before it became a spherical gaseous star, we may take as the heat lost from time $\mathrm{T} = 0$ when the radius was $\mathrm{R}_0$ to the present time T, when the radius is R

$$(a-\beta)\mathrm{M}^2\left(\frac{1}{\mathrm{R}}-\frac{1}{\mathrm{R}_0}\right) \quad . \ . \ . \ . \ . \ . \ . \ (16)$$

In the mass M there are surfaces whose areas are proportional to $\mathrm{R}^2$, and whose temperatures are proportional to $\dfrac{\mathrm{M}}{\mathrm{R}}$. I shall assume as quite reasonable, that

$$\left.\begin{array}{r}\text{Total radiation per}\\ \text{year from a star}\end{array}\right\}\propto \text{areas}\times(\text{temperatures})^n \quad . \ (17)$$

where $n$ is some constant.

It may be worth while here to use with this the assumption that our sun, when gaseous, radiated heat of the same amount every year; of course H of (15) or (16) is then proportional to time. (15) is the age of the sun from some zero of time until it had the radius R; (16) is the time taken to contract from radius $R_0$ to radius R.

Using (17),

$$\text{Rate of total radiation} \propto R^2\left(\frac{M}{R}\right)^n \quad . \quad . \quad . \quad . \quad (18)$$

we see that $n$ must be 2 for our sun. In our state of ignorance of the phenomenon of radiation from a star it may be presumptuous in me to say that this would be a very reasonable *à priori* assumption. Namely that rate of radiation is proportional to surface and square of average temperature. Anyhow it makes the task of pursuing the uniformitarian assumption less thankless.[1]

For any star then the total radiation in unit time is proportional to $M^2$, and hence the time taken by any gaseous star in contracting from radius $R_0$ to radius R is

$$T \propto \frac{1}{R} - \frac{1}{R_0} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (19)$$

being the same for any star, whatever its mass may be. How it depends on the nature of its material we do not know, as we are basing these speculations on an assumption as to the sun's radiation. Or counting *age* from some period in the nebulous state, which it is not easy to define.

$$\text{temperature of star} \propto \text{age} \times \text{mass} \quad . \quad . \quad . \quad . \quad (20)$$

We see that stars get to have higher and higher temperatures as they get older, until they cease to behave as gaseous bodies throughout. The temperature outside is 0. The depth below the surface at which there exists a layer of a particular temperature, say 5000° Cent. absolute, is proportional to $R^2/M$, or if our rule as to time is right, the depth is inversely as the mass of a star multiplied by the square of its age. In a very old, massive star the layer at 5000° is very close to the outside.

It seems to me that this is an important thing. A young star, a truly gaseous star, has great depth of radiating layer. I mean it is probably only at great depths from the free surface that we find the layer from which a continuous spectrum comes. I take it that it is only during collision of molecules that a continuous spectrum is given out; in the free-path state of a molecule it radiates its own light only. Great density and high temperature conduce to the giving out of the continuous spectrum. In old stars, like our sun, the layer of stuff capable of giving out white light is comparatively near the surface of the star. I can imagine a comparatively young star long before its heat energy is a maximum, not radiating energy very fast, but rather giving out bright line spectra light from the greater part of its area; in fact from all but its central parts.

I am very ignorant of your subject, but I take it that any star gives out a continuous spectrum with lines. The continuous spectrum is strong, and the lines relatively dark, in old stars; the continuous spectrum is weak, and the lines bright, in new stars. In both cases the continuous spectrum is most intense, and the lines least intense at the central parts of a star. If a star is very new, so that it is not all gas, it will probably not be spherical, and one may have spectra quite different in different places and at different times.

[1] If total radiation from a star is proportional to surfaces × the $n$th power of temperatures

$$\frac{dH}{dT} \propto M^n R^{2-n}$$

but from (16),

$$\frac{dH}{dT} \propto -\frac{M^2}{R^2}\frac{dR}{dT}$$

Putting these equal and integrating we find T as the time since the star was of radius $R_0$

$$T \propto \left(R_0^{n-3} - R^{n-3}\right)\frac{M^{2-n}}{n-3}$$

I. Thus if $n=1$,

$$T \propto M\left(\frac{1}{R^2} - \frac{1}{R_0^2}\right)$$

It follows from this assumption that the rate of increase of temperature per annum is proportional to $\frac{\text{Mass}}{\text{temperature}}$.

II. If $n=2$ as above,

$$T \propto \frac{1}{R} - \frac{1}{R_0}.$$

It follows from this that the rate of increase of temperature per annum is constant and is proportional to the mass of the star.

III. If $n=3$,

$$T \propto \frac{1}{M}\log\frac{R_0}{R}.$$

It follows from this that the temperature increases with time by the compound interest law; that is, the rate of increase of temperature per annum is proportional to the mass × temperature.

IV. If $n=4$,

$$T \propto \frac{1}{M^2}\left(R_0 - R\right).$$

In this case the rate of increase of temperature per annum is proportional to the square of the temperature.

Suppose it to be assumed that the radiation is mainly from an outer layer, that this layer increases in temperature from $t=0$ at its outer surface to $t=t_1$ at its inner surface, the depth or thickness of it is

$$D \propto \frac{\sigma R^2}{M}.$$

Thus the thickness of the layer is greater with stuff like Hydrogen than with Oxygen. As we really know nothing about how the total radiation from such a layer depends upon the thickness, I cannot use this in my calculations. It is however worth noting that from equal surface areas of layers all with the same range of temperature but of different depths or thicknesses D, the radiation per second $\propto \left(\frac{M}{D}\right)^{n/2}$.

Thus in the case above, in assuming $n=2$, we are really assuming that the radiation from unit area of layer is inversely proportional to its thickness.

Suppose we speak of the depth D′ below the surface to reach a layer of a particular density $\rho_1$ then

$$D' \propto \frac{R^{2\frac{1}{2}}}{M^{\frac{1}{2}}}$$

the depth being independent of whether the stuff is Oxygen or Hydrogen.

### *Stars in General.*

I suppose that many people will think the above speculation to be fairly safe. It is correct on the assumptions. One may apply it to any star until the central density approaches 0·1 or one-tenth of that of water or even more. In the case of our sun, the theory may have been applicable from the time when his radius was twenty times what it is now until it was five times what it is now. Near the surface I assume the density and temperature to be very small, and probably there is no substance that will behave as a perfect gas near the zero of temperature even if its density is also nearly zero. But as the mass of stuff in this condition is small, we may, I think, use our hypothesis. Besides, we are neglecting more important things; many possible conditions difficult to specify; heterogeneity; violent convective rushing of stuff like iron vapour to the places of low temperature where it may undergo sudden condensation and fall as iron hail over large regions; also, intense electrical actions are certainly taking place. All this may be said to be superficial, affecting only a small portion of the whole mass. On the whole, then, we may take our theory of gaseous stars to be applicable to some portion of the life of any star.

I am on much less safe ground when I try to trace the history of a star after its material ceases to behave as a perfect gas, and yet, as I take it, this is very much the longest part of its career. I may only vaguely speculate on its long or short life as a nebula; as a confused mass of streams of meteors in which every collision generates gaseous masses at all kinds of temperatures; its record is fairly clear from the time [if there ever is such a period in the truly gaseous state] when it assumes the spherical shape [in all cases I am neglecting rotation] and gets hotter and hotter and smaller and smaller. If the law of radiation is the same in any star as in our sun, and if we take one year's loss of heat energy by our sun as the unit of energy; if our unit of mass is the mass of our sun and if the sun's present radius is our unit of length, I

find[1] [using Lord Kelvin's popular lecture figures for the present solar radiation] for any star,

$$W = 36 \times 10^6 \frac{M^2}{R} \quad \ldots \ldots \ldots \quad (21)$$

$$h = 32{\cdot}4 \times 10^6 \frac{M^2}{R} \quad \ldots \ldots \ldots \quad (22)$$

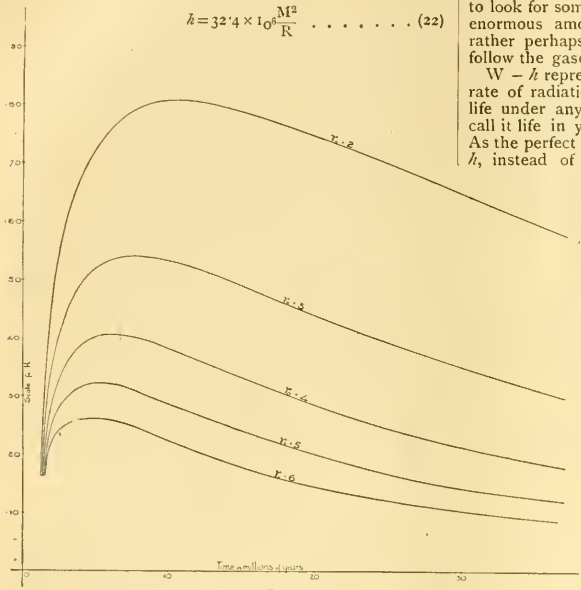

FIG. 1.

I must say that when Mr. Lister first worked out this value of $h$ for me I was greatly surprised, for it has been generally thought that $h$ is always, not merely much less than W, but exceedingly less. But there can be no doubt (see also my final statement) that in a gaseous star the intrinsic or thermodynamic energy in the star is a very large fraction of the whole energy of the gravitating matter. Indeed it is so large that one is tempted to look for some greater original store to account for the enormous amount of radiation which takes place, or rather perhaps to assume that no radiating mass can follow the gaseous law.

W − $h$ represents life in years if we assume a uniform rate of radiation. It has an obvious connection with life under any assumption that we may make. Let us call it life in years, and continue to consider our sun. As the perfect gas law ceased more and more to be true, $h$, instead of increasing steadily, reached a limiting value and then diminished again, so that eventually $h$ must become zero. In what state is our sun now? Is it still very much like a gas throughout, and getting hotter? It is too much to assume for stuff that would be 50 per cent. greater in density than platinum at the centre. In all probability the change from the law of (22) began before R was 5, was quite marked when R was 4, and $h$ reached its maximum value when R was 4 or $3\frac{1}{2}$ or 3. It is quite certain that $h$ must reach a maximum value in any star, and afterwards diminish gradually, and the simplest mathematical formula expressing this fact may be used instead of (22) to give us useful suggestions in regard to the history of our sun. Such a simple formula is

$$h = 0{\cdot}9W \Big/ \left(1 + \frac{R_0^2}{R^2}\right) \quad \ldots \ldots \quad (23)$$

If R is very great (23) is the same as (22). When R is $R_0$, $h$ reaches a maximum value, and for smaller values of R, $h$ diminishes. The following tables have been calculated, a different assumption being made for each. W is calculated from (21). $R_0$ is the radius of our sun (as compared with its present radius) when $h$ was a maximum. Thus the table headed $R_0 = 4$ gives W and $h$, T and D on the assumption that our sun reached its hottest condition when it was of 4 times its present radius. I take $W - h$ and call it T the age or Time in years, but all these values of T may be multiplied by some constant, W, $h$ and T are given in millions.

D is the depth (from surface) of a layer of stuff, say 10,000° C., taking the depth of such a layer at present as 1.

Fig. 1 shows how the intrinsic heat energy of our sun

TABLE II.—*Based on five different assumptions as to the time when our Sun was at its hottest. Also assuming Radiation at present rate.*

| Age of Star in millions of years. | $R_0=6$ | | | | $R_0=5$ | | | | $R_0=4$ | | | | $R_0=3$ | | | | $R_0=2$ | | | |

| 34·1 | 34·98 | 0·88 | 1·028 | 1·057 | 35·36 | 1·26 | 1·018 | 1·037 | 35·99 | 1·89 | 1·000 | 1·000 | 37·26 | 3·16 | ·9754 | ·9346 | 40·03 | 6·03 | ·9024 | ·8162 |

[1] In C.G.S. units (13) and (14) give, if the stuff is like oxygen or hydrogen whose $\gamma$ is 1·4,

$$h = 6{\cdot}36 \times 10^{-8} M^2/R,$$
$$W = 7{\cdot}079 \times 10^{-8} M^2/R.$$

In obtaining these numbers Mr. J. Lister took the values of $\theta$ deduced from Mr. Homer Lane's curves before we discovered Lord Kelvin's paper. It will be seen that he gets $h/W = {\cdot}9$. It is easy to show that this ratio must really be 0·83, but I am not concerned in getting mathematical accuracy here. If our $\gamma$ is slightly different from 1·4, we may have the above numbers.

has varied with its age on the above assumptions, which are all uniformitarian. The curves and table will suit any star if the unit of energy employed is the heat radiated per year by the star. If a star is twice the mass of our sun, the unit of energy is four times as great as in the case of our sun. A curve connecting R and time is

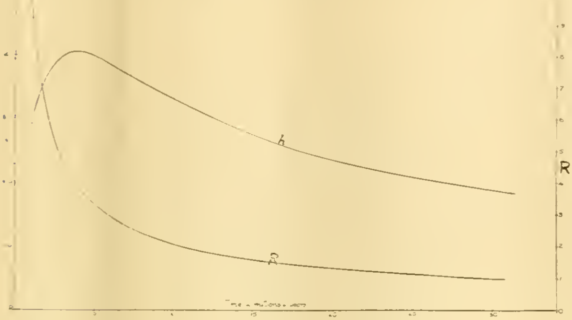

FIG. 2.

the same for all stars, and in the table the sun's present radius is the unit for R.

I take the critical size or size of maximum $h$ in a star to depend upon $\rho_0$ the central density; if then the critical radius of our sun was 4 (or 4 times its present radius), the critical radius of a star whose mass is M times that of our sun was $4\sqrt[3]{M}$.

*Non-Uniformitarian Assumptions.*

The numbers in Table II. enable us to find what any assumption as to rate of radiation leads to. Thus, instead of assuming a constant amount of radiation every year, let us assume in the case of our sun that the rate of radiation at any time was always proportional to $h$. Let us take the supposition that $h$ was greatest for our sun when R was four times its present value. Then as T in the table is no longer to be called time, as it is really $W-h$; let $t$ be time; $c$ being some constant.

$$\delta T = ch.\delta t.$$

Hence

$$t=\int\frac{dT}{ch}.$$

It is quite easy to plot the curve whose ordinate is $\frac{1}{ch}$ and whose abscissa is T of the table; in this way using a value of $c$, which is suitable, I find

TABLE III.—*Rate of Radiation Proportional to* h.

| $W-h$. | $\frac{1}{h}$ | Age in millions of years. $t$. | R. | $h$. |
|---|---|---|---|---|
| 1 | ·342 | 1·0 | 9·18 | 2·92 |
| 2 | ·280 | 1·78 | 6·52 | 3·57 |
| 3 | ·260 | 1·45 | 5·27 | 3·85 |
| 4 | ·250 | 2·09 | 4·51 | 4·01 |
| 5 | ·246 | 2·71 | 3·99 | 4·06 |
| 6 | ·248 | 3·33 | 3·58 | 4·03 |
| 8 | ·256 | 4·58 | 3·02 | 3·91 |
| 12 | ·284 | 7·28 | 2·32 | 3·52 |
| 18 | ·338 | 11·92 | 1·71 | 2·96 |
| 24 | ·410 | 17·53 | 1·36 | 2·44 |
| 34 | ·528 | 29·26 | 1·00 | 1·89 |

The values of $h$ and of R at the various periods in the life of our sun (or any star) are given in Fig. 2.

The curve for $h$ shows also the rate of radiation. It is assumed to have once been more than twice as great as at present in our sun.

Any other assumption may be tried easily. I myself prefer to think that as a star gets older and as its white light radiating layer gets nearer and nearer its outer surface, its rate of radiation increases. It is quite possible as I have shown in NATURE (p. 582, April 1895), that our sun radiated very little energy during long periods in the past. Without taking an extreme case I will assume that the rate of radiation gets greater just in proportion to age and so find the following table.

TABLE IV.—*Rate of Radiation Proportional to Age of Star.*

| $W-h$. | Age in millions of years. $t$. | R. |
|---|---|---|
| 0·4 | 7·95 | 16·34 |
| ·8 | 11·26 | 10·2 |
| 1·5 | 15·42 | 7·57 |
| 2·0 | 17·8 | 6·52 |
| 3·0 | 21·8 | 5·27 |
| 4·0 | 25·2 | 4·51 |
| 5·0 | 28·1 | 3·99 |
| 6·0 | 30·8 | 3·58 |
| 8·0 | 35·6 | 3·02 |
| 12·0 | 43·6 | 2·32 |
| 18·0 | 53·4 | 1·71 |
| 24·0 | 61·7 | 1·36 |
| 34·0 | 73·4 | 1·00 |

The values of $h$ and of R at the various periods in the life of our sun are given in Fig. 3.

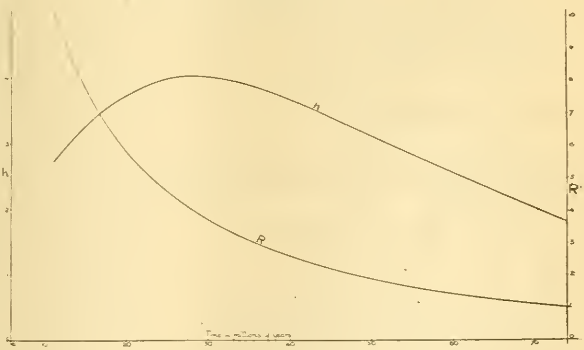

FIG. 3.

On no one of the above assumptions can I see that it is possible to give even a probable limit to the future life of our sun as a light-giving body.

*Energy in a Spherical Mass of Gas.*

I end this long letter with a very curious statement concerning gaseous masses in space, and I am sorry that my own proper work is demanding so much of my attention that I must leave the following very definite statement without applying it, as I see that it may be applied, to the study of the physical properties of many gases. We have seen that, under convective equilibrium, there is an outside radius beyond which there is no stuff

existing. The following statement does not assume convective equilibrium; an outside radius, R, is assumed to exist.

Let temperature, pressure, &c., be functions of $r$. If $m$ is the total mass bounded by the spherical surface of radius $r$,

$$\frac{dp}{dr} = -a\frac{m}{r^2}\rho \quad . \quad . \quad . \quad . \quad . \quad . \quad (24)$$

$$m = 4\pi\int_0^r r^2\rho \,.\, dr \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (25)$$

the stuff being a perfect gas,

$$\rho\sigma t = p \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (26)$$

If $k$ is the specific heat (in ergs) at constant volume, the total intrinsic energy of the mass is

$$h = 4\pi k\int_0^R r^2\rho t \,.\, dr,$$

$$h = \frac{4\pi k}{\sigma}\int_0^R pr^2 \,.\, dr \quad . \quad . \quad . \quad . \quad . \quad . \quad (27)$$

The work that would have to be done in taking successive layers to an infinite distance is

$$W = +a\int_0^R \frac{m}{r}4\pi r^2 \,.\, dr \,.\, \rho = +4\pi a\int_0^R \rho mr \,.\, dr \quad . \quad (28)$$

Now (24) is

$$\rho am = -r^2\frac{dp}{dr},$$

so that

$$W = -4\pi\int_0^R r^3\frac{dp}{dr} \,.\, dr = -4\pi\int_{p_0}^0 r^3 dp \quad . \quad . \quad (29)$$

Now in (27)

$$\int_0^R pr^2 . dr = \Big[\tfrac{1}{3}pr^3\Big]_0^R - \int_{p_0}^0 \frac{r^3}{3}dp.$$

The bracket term is 0, as $r$ is 0 at the centre, and $p = 0$ at the surface. Hence 27 is

$$h = -\frac{4\pi k}{\sigma}\int_{p_0}^0 \frac{r^3}{3}dp.$$

Dividing by (29) we have

$$\frac{h}{W} = \frac{k}{3\sigma}$$

Now in gases, if K is specific heat at constant pressure $\sigma = K - k$ so that

$$\frac{h}{W} = \frac{k}{3(K-k)} = \frac{1}{3(\gamma - 1)}$$

If

$$\gamma = 1\tfrac{1}{3}, \; h = W$$

If

$$\gamma = 1\cdot4, \; h = \cdot833W$$

Here are very definite astonishing statements!

I must confess that I do not understand how if $\gamma = 1\frac{1}{3}$ we can have $h = W$. It seems to mean that if a mass of this kind of gas gravitates by itself from an infinite distance it retains all its energy. But such gas must surely be imagined to be radiating heat, as it is not at zero temperature. Where can it get such heat? I come to the conclusion that there must be atomic energy available somehow in it, even when we imagine the molecules at an infinite distance from one another, or else there is no such gas possible. *I say* that no substance for which $\gamma = 1\frac{1}{3}$ can behave as a perfect gas.

You will notice that we do not need to imagine our stuff in a state of infinite diffusion. If a gaseous star changes its size or the arrangement of its stuff, the gravitational work done is exactly equal to the additional intrinsic heat energy in the star if $\gamma$ is $1\frac{1}{3}$. The paradox is greater if we think of coloured diatomic gases such as chlorine, which have values of $\gamma$ less than $1\frac{1}{3}$. We must either assume that there is more energy available than mere gravitational energy, or else that such substances cannot really behave as perfect gases. [It is to be remembered that by a perfect gas I do not merely mean that $p/t\rho$ is constant, but that $k$, the specific heat at constant volume is constant, a statement which does not follow from the first.] It is some time since I have come across a statement which looks better worth study than this one.

## *WILLIAM HENRY FLOWER, K.C.B., F.R.C.S., LL.D., D.C.L., Sc.D., F.R.S., F.Z.S., F.L.S.*

THE distinguished naturalist whose death has recently occurred was the second son of the late Mr. Edward Fordham Flower, the founder of the well-known brewery at Stratford-on-Avon, and dear to all lovers of animals on account of his crusade against the bearing-rein. Sir William Flower was born in November 1831. He was educated at private schools and at University College, London, where he took Sharpey's gold medal in Physiology, and Grant's silver medal in Zoology. He became M.B. of the University of London in 1851, and joined the Medical Department of the Army in 1854, serving in the Crimea, where his health broke down. On his return to England he became Demonstrator of Anatomy at the Middlesex Hospital, and Curator of the Museum, intending to practise as a surgeon. Here he published his first work, "Diagrams of the Nerves of the Human Body," and also wrote in Holmes' "System of Surgery" on "Injuries of the Upper Extremities."

In 1861, at the age of thirty, he was appointed to succeed Queckett as Curator of the Hunterian Museum at the College of Surgeons, and later became Hunterian Professor. Thenceforward he abandoned professional work for purely scientific pursuits. Twenty years later, when he received the Royal medal of the Royal Society, the President stated with justice that "it is very largely due to his incessant and well-directed labours that the museum of the Royal College of Surgeons at present contains the most complete, the best ordered, and the most accessible collection of materials for the study of vertebrate structures extant."

Two years later (in 1884), on the resignation of Sir Richard Owen, Prof. Flower was appointed Director of the new Natural History Museum in the Cromwell Road, where he was incessantly occupied with the arrangement and development of the collections until failing health necessitated his resignation, which took effect in October 1898. Unhappily he did not long enjoy the rest and leisure which he had so well earned by a life of unusual industry and devotion to public work.

His services in the cause of knowledge were recognised by many honorary degrees from Universities, and by his election as a Correspondent of the Institute of France. He was made C.B. in 1887, and K.C.B. in 1892, and was President in 1889 of the British Association for the Advancement of Science.

The mere enumeration of the incidents in a man's life does not tell very much about the nature and value of his work. Sir William Flower's chief work was in two directions: firstly, as a director and original artist in museum management; secondly, as an investigator and discoverer in the comparative anatomy of the Mammalia. Besides these two chief lines of work, there were others to which he gave time and care. He was not unheedful of the popular demand for instruction and guidance by lectures. He frequently appeared at the Royal Institution and the London Institution, and always had a weighty and well-considered discourse to deliver. The most original and, from a social point of view, the most important of these was one on "Fashion in Deformity," in which he gave very strong support to those who dis-

approve of tight-lacing, high-heeled shoes, and other monstrosities of clothing. Another way in which Sir William Flower gave voluntarily a large amount of valuable work to the community was as President first of the Anthropological Institute, and then of the Zoological Society—a post which he held until his death. Such services in our scientific societies are given without any remuneration, and they can only be repaid by the grateful acknowledgment of those interested in the progress of the branches of science thus benefited.

To revert to the two chief lines of Sir William Flower's life-work. He first became generally known in the scientific world by joining the band of young anatomists who supported Huxley in his rejection of the statements made by Owen as to the differences between the brain of man and of apes. Like the other members of that group—Turner, Humphrey, and Rolleston—Flower published an important contribution to the controversy. This memoir, entitled "Observations on the Posterior Lobes of the Quadrumana," was printed in the *Philosophical Transactions* in 1862; and about the same time Flower wrote also on "the brain of the Siamang" in the *Natural History Review*. His most numerous contributions to anatomical science relate to the Cetacea, which was his favourite group. After the deaths of P. J. Van Beneden and Gervais, he was only rivalled in his knowledge of whales by Sir William Turner, of Edinburgh. It was a special satisfaction to Flower to have been able to complete the admirable exhibition of whales at the Natural History Museum before his retirement—an exhibition which is not only unequalled, but is not even attempted in any other museum in Europe or America. Next to the Cetacea, the subject on which Flower worked and wrote most was physical anthropology. His catalogue of the anthropological series in the museum of the Royal College of Surgeons and its introductory chapter have served as classics to English anthropologists, and are the result of an immense amount of patient research. Separate papers by him on the osteology of the Andaman Islanders and of the Fijians are of great value on account of the large amount of material dealt with, and the caution and judgment shown in drawing conclusions. Caution and reticence in generalisation certainly distinguish all Flower's scientific writings. Whilst he was on this account necessarily not known as the author of stirring hypotheses, his statement of fact gained in weight by his reputation for judgment and accuracy. The most important discovery in anatomical science which we owe to him is that of the existence of but one successional molar in the marsupial Mammals. This sharply defined and important fact was only one, but the most striking, of the results of a long, conscientious and painstaking study of the dentition of the Mammalia. The next most striking discovery which we owe to Flower seems to me to be the complete and convincing demonstration that the extinct marsupial called *Thylacoleo carnifex* by Owen was not a carnivor, but a gnawing herbivorous creature like the marsupial rats and the wombat—a demonstration which has been brought home to the eye even of the unlearned by the complete restoration of the skull of Thylacoleo in the Natural History Museum prepared by Dr. Henry Woodward. Another thoroughly original and elaborate piece of work which should, I think, be especially remembered in attempting to survey Flower's anatomical labours, is the attempt to bring order and system into the study of the forms presented by the lobes of the liver in the Mammalia, an effort which has not, perhaps, as yet borne all the fruit of which it is capable.

In such a brief notice as the present a complete bibliography of Sir William Flower's contributions to anatomical science cannot be given, but a fair notion of his great activity in research can be obtained from a selected list. Relating to the Cetacea, I would cite the following papers from the *Proceedings* of the Zoological Society:—On a lesser Fin-whale (Balænoptera rostrata) stranded on the Norfolk Coast (1864); the skeletons of Whales in the Principal Museums of Holland and Belgium (1864); on a new species of Grampus from Tasmania (1864); on Physalus Sibbaldii (1865); on Pseudorca meridionalis, 1865; on a Fin-whale stranded in Pevensey Bay (1865); the probable identity of Balænoptera Carolinæ and Physalus Sibbaldii (1868); on the Whales of the genus Hyperoodon (1882); on the Characters and Divisions of the Family Delphinidæ (1883); then in the *Transactions* of the same Society, the fine illustrated papers on the skeleton of Inia Geoffrensis (1869); on the osteology of the Cachalot (1869); on the skeleton of a Chinese White Dolphin (1872); on Risso's Dolphin (1873); on recent Ziphioid Whales (1878); on two species of British Dolphins (1880); and the translation of and introduction to Eschricht's treatise published by the Ray Society. Also in the *Proceedings* of the Royal Institution, Whales Past and Present, and their probable origin (1883).

Relating to physical anthropology, Sir William Flower's most important works are the following:—The Catalogue of Specimens in the Museum of the Royal College of Surgeons, 1879 and 1884 (already referred to above), in the *Journal* of the Anthropological Institute; the osteology of the natives of the Andaman Islands (1879); the osteology of the Fijians (1880); the osteology of the Mallicolese (1881); the aims and prospects of the Study of Anthropology (1884); the Classification of the Varieties of the Human Species (1885); on the size of Teeth as a character of Race (1886); in the *Proceedings* of the Royal Institution (a Friday evening discourse) on the Native Races of the Pacific (1878); and in the Manchester Science Lectures, a discourse on the aborigines of Tasmania (1866).

Ranging over other groups of Mammals, I would cite the following papers:—On a newly-discovered extinct Mammal (Homalodontotherium) from Patagonia (*Phil. Trans.*, 1873); Description of the skull of a species of Halitherium from the Red Crag of Suffolk (*Quart. Journ. Geol. Soc.*, 1874); on the remains of Hyænarctos in the Red Crag of Suffolk (*ibid.*, 1877). From the *Proceedings* of the Zoological Society: papers on the anatomy of Galago (1862); of Pithecia monachus (1862); on the brain of the Echidna (1864), on the brain of the Red Howling Monkey (1864); on the anatomy of Hyomoschus (1867); on the development of the teeth in the Armadilloes (1868); on the characters of the base of the cranium and the classification of the order Carnivora (1869); on the anatomy of Proteles cristatus (1869); and on that of Aelurus fulgens (1870); and of the two-spotted Paradoxure (1872); and of the Musk Deer (1875); on the cranial and dental characters of the existing species of Rhinoceros (1876); and on the mutual affinities of the animals composing the order Edentata (1882).

Of a more general character are his articles in the "Encyclopædia Britannica":—On the anatomy and zoology of the Horse, Kangaroo, Lemur, Lion, Mammalia, Mastodon, Megatherium, Otter, Platypus, Rhinoceros, Seal, Swine, Tapir, &c. These have formed the basis of a very useful volume on the Mammalia published by Messrs. Black, whilst the compact little volume on the osteology of the Mammalia by Sir William Flower is known to all University students. The last volume which came from his pen is one of the best and most interesting, namely that called "The Horse: a study in natural history," published in 1892.

Having thus indicated (and only "indicated" by no means "enumerated" or "fully set down") the labours of Sir William Flower in anatomical research, I pass to a brief consideration of his work as a museum curator, which probably took up more of his time and energy than he was able to give to original investigations. This

is most certainly true of the second portion of his scientific life, which dates from his appointment in 1884 to the directorship of the Natural History Museum, and was preceded by twenty years of work as Hunterian Curator. There can be no doubt in the mind of any man who is acquainted with the present condition of the public galleries of the great museums of natural history in Europe, and with the condition which characterised those of similar institutions in Great Britain previously to the year 1864, that a very great and important change for the better was effected by Flower, first of all at the College of Surgeons, and later in accordance with a further development of his ideas, at the Natural History Museum (British Museum, Natural History). The arrangement and exhibition of specimens designed and carried out by Flower in both instances was so definite an improvement on previous methods, that he deserves to be considered as an originator and inventor in museum-work. His methods have not only met with general approval, and their application with admiration, but they have been largely adopted and copied by other curators and directors of public museums both at home and abroad. In his address as President of the British Association, and also in an address to the Museums Association, Sir William Flower has explained in some detail the theory which he held with regard to the proper selection and arrangement of objects in a public museum. The general conception which Sir William Flower had formed was accepted and developed in detail by that gifted and genial museum-director, Brown Goode, of Washington, U.S.

It is simple enough and convincing. But the work of the museum curator consists not merely in framing theories of museum organisation and arrangement: the more important part of his work is the putting of such theories into practice. To do this, energy and patience in the surmounting of obstacles are necessary, and perhaps as much as or more than any other quality—the artistic sense. Sir William Flower possessed this last quality in a remarkable degree. No pains were spared by him in selecting the proper colour for the background or supports of the specimens exhibited in a case, or in effectively spacing and balancing the objects brought together in one field of view. He took the greatest pains to make the museum under his care a delight to the eye, so that the visitor should be charmed by the harmony and fitness of the groups presented to his notice, and thus the more easily led to an appreciation of the scientific lesson which each object has to tell. There are public galleries in some of the natural history museums of Europe where the specimens are so crowded and ill-placed, where the lighting is so badly designed and the prevailing colour of case and wall so depressing, that the main purpose of the exhibition is defeated by the fact that the visitor becomes seriously attacked by headache before he has been able to ascertain what there is for him to look at, or why he should look at anything at all, in the appalling accumulation spread before him. It was Sir William Flower's merit to have introduced a better way, and so far as opportunity and the brief fourteen years of his directorship allowed him to do so, he put that better way into practice at the national museum of natural history. The first great principle upon which Sir William Flower insisted was that the possessions of a great museum of natural history must be divided into two distinct parts—to be separately dealt with in almost all respects—viz. the public or show-collection, and the special or study-collection, not exhibited to the general public, but readily accessible to all investigators and specially qualified persons. The latter collection, he insisted, should have at least as much space devoted to it as the former. In this way the public galleries would (he showed) be cleared of the excess of specimens which, nevertheless, the museum must carefully preserve for the use of specialists. Then, further, Flower held that every specimen placed in the public or show-collection should be there in order to demonstrate to the visitor some definite fact or facts, and so should be most fully visible, isolated rather than obscured by neighbouring specimens, and ticketed with an easily-read label stating clearly and simply the reason why it is worth looking at—that is to say, what are its points of interest. He would thus have reduced very much in *number* the specimens commonly exhibited in natural history museums, and have increased the *interest* and *beauty* of each specimen selected for the public eye. Another principle which he often insisted upon—but was not able to put fully into practice owing to long-standing arrangements in the museum over which he presided—was that in the public galleries the skeletons of animals should not be placed in one room and the stuffed skins in another, and the soft parts in a third, and the fossilised remains of extinct allied animals in a fourth more or less remote chamber; but that the visitor should see, side by side, the stuffed or otherwise preserved animal (mammal, bird, reptile, fish, mollusc, insect, worm or polyp) and its skeleton and important parts of its internal structure and the remains of its extinct allies. Thus, there would be, not three or four separate zoological collections for the amazed visitor to traverse and bring into correlation by mental effort, but one only, in which the story of each animal is told as completely as possible in one connected exhibit. It is simply a fact that the "art of arranging museums for the public" is in its infancy, and that it was mainly, if not entirely (so far as natural history is concerned) founded by William Henry Flower. Like other originators, he did not live to see the principles which he advocated fully acted upon, nor did he expect to do so. He knew that time is a necessary element in such developments. But he has left an enduring mark on what we may call "museum policy." His teaching and performance are producing, and will continue to produce, progress towards the realisation of his ideals.

Sir William Flower did not train or produce any pupils. He did his own work with his own hands, and I have the best reason to know that he was so deeply shocked and distressed by the inaccuracy which unfortunately crept into some of the work of his distinguished predecessor Owen, through the employment of dissectors and draftsmen whose work he did not sufficiently supervise, that he himself determined to be exceptionally careful and accurate in his own records and notes. In later years, he had the assistance of young anatomists in making the beautiful preparations which are placed in the central hall of the museum. One of his assistants, Mr. Wray, whilst preparing, under Sir William Flower's direction, specimens for the museum to exhibit the disposition of the feathers in the wings of birds, discovered the strange and puzzling fact that the fifth cubital quill is apparently absent—that is to say, there is a gap where it should be—in whole orders and families of birds, whilst it is present in other orders and families. The discovery of the wide-spread occurrence of aquintocubitalism—as it has been called—was thus made in Sir William Flower's work-room, and in connection with his scheme of museum exhibition.

It is well to place on record that Sir William Flower was a convinced Darwinian. At the meeting of the Church Congress at Reading in October 1883, he had the courage to open a discussion on "Recent Advances in Natural Science in their relation to the Christian Faith," his expressed object being to mitigate the prejudices of many of the strongest opponents of the doctrine of evolution amongst the clergy.

Whilst discharging in so many different ways important public duties, and holding up amongst scientific men a high standard of accurate work and unremitting devotion

to the progress of zoological knowledge, Sir William Flower found time to extend very largely among the educated classes an interest in the aims and results of zoology by the willing courtesy with which he received visitors at the Museum in Cromwell Road, and explained its contents. His interest in his work there was so sincere that no zoologist ever asked in vain for his help and advice in museum matters. He was so earnest in carrying out his new devices for the effective exhibition to the public of zoological specimens that even on his busiest days he would find a few minutes to show his latest improvements to one who sympathised with his aims and believed in his methods.

Personally, I owe very much to him in this way. I am glad also to be able to acknowledge here the help which he gave to me by supporting in a valuable letter, which was printed and circulated at the time, the re-arrangement of the zoological and anatomical collections in the University Museum at Oxford, which I had proposed and was enabled subsequently to carry out—largely in consequence of the weighty opinion which Sir William Flower gave in its favour. E. RAY LANKESTER.

## THE DUTIES OF PROVINCIAL PROFESSORS.

DURING the past twenty years numerous centres of university education have grown up all over our country, and much public money has been spent in their endowment. Some of these colleges have already risen to the rank of universities with the power of conferring degrees; others are eagerly pressing forward in the same direction in the hope of competing with their more fortunate rivals. If this multiplication of universities is not to result in lowering the prestige of British university degrees, but to enable us to compete in the matter of scientific education with foreign countries, it is of the utmost importance that the professorial staffs of our younger university colleges should be placed under the most favourable positions for establishing the reputations both of themselves and of their colleges in the matter of higher study and research. The time appears to have come when we must face much more boldly than hitherto the question whether the conditions attaching to provincial professorships and lectureships, even in some of our most successful university colleges, are conducive or inimical to progress in such respects.

In calling attention to the serious and, to our mind, unnecessary disadvantages under which provincial professors are often placed at the hands of their Councils or Governing Boards, our remarks must be understood to be based on a considerable number of experiences of which we have gathered details during some years.

A foreign professor may only lecture five hours a week, and devote the rest of his time to research, and yet be regarded as discharging his duties fully and efficiently. Under such a system German professors have filled their class-rooms with the best students drawn from all parts of the world, German degrees are rising in public estimation year by year, English students are going out of their own country for the higher training they cannot obtain at home, and we are mainly indebted to Germany for our standard literature on every branch of science.

In America university development is more recent, but the majority of universities are lavishly staffed with professors and assistant lecturers, who thus have ample time for research; and the system has been introduced of giving these teachers one free year in seven, in order that they may be able the better to keep themselves abreast with the most recent developments of their science. Under such conditions, America is rapidly pressing forward in scientific research, and American text-books are slowly and surely finding their way into English class-rooms.

As instances of what one university can do in promoting research, even in a single department of science, we need only call attention to the *Communications* from the Physical Laboratory of the University of Leiden, published periodically in English, or the *Physical Review*, brought out under the auspices of Cornell University.

Our modern centres of university education are largely bound down to the policy of attracting the greatest number of students, not by the reputations of their professors, but by the attractions they offer in small bursaries and in facilities for cheaply acquiring pass degrees. Under this system a professor may give fifteen lectures a week or more, and spend most of the rest of the day in the laboratory; but there is no limit to the extraneous work required of him by his Council or Governing Board, beyond that research work forms no part whatever of his obligations. We do not deny that good work is done in this country by many provincial professors, but it is often done under extreme difficulties, and many others are debarred from taking that place in the scientific world for which their abilities qualify them.

With regard to the lectures themselves, these are almost exclusively limited by the syllabus of examinations for pass degrees. Matriculation preparation forms a heavy item in the work of most departments, and one to which great importance is commonly attached. It is the duty of the professor not so much to push forward his best students as to adapt his lectures to the requirements of the average student, and to bring as many as possible up to pass standard. He is held responsible for the attendance and diligence of his students in class, and is bound to make records of these matters; while out of class he and his colleagues are jointly responsible for general discipline, even extending to the rules of athletic clubs. He is required to set and correct exercises and examination papers at frequent intervals. If students have not followed his lectures properly he is expected, often at short notice, to provide tutorial instruction without limit to those whose chances of passing are in danger—an arrangement, by the way, hardly calculated to ensure students giving their best attention to professorial lectures.

We do not imagine that any professor, if left to himself, would be wanting in willingness to give a large amount of his private time to helping students over difficulties, and making his lectures convey the greatest amount of instruction with the least amount of work. But if a professor makes a conscientious stand against cramming, or puts any personality into his professorial work, he runs the serious risk of losing at a few weeks' notice the post he has held for years, at the hands of a Governing Board who misinterpret his action because they have no knowledge of the conditions attaching to a sound teaching of his subject. In such cases students, who are more concerned about getting a degree than about the thoroughness of their training, may be called on to give evidence against their professor. We have knowledge of several instances in which colleges have on insufficient grounds lost the services of men who have been doing good work for them, whose teaching has been acknowledged to be successful, and who, under less disadvantageous conditions, would have done them credit by their scientific work.

The practical result of this system is that our modern university centres, whether chartered or not, are devoting their endowments to competing for cheap pass degrees with one another, and with private institutions and tutors who prepare for London University and similar examinations. The students spend the whole day in class-rooms and in laboratories, and when they have done the exercise work required by their teachers, the day is gone and they are too tired to *think over* what they have learnt. Their professors are thus required to do the thinking for them.

After three years in the mill the students obtain a degree, gained under conditions calculated to minimise what should be one of the most important features in any university training: the learning to think and overcome difficulties for oneself. There is thus a growing annual output of graduates of both sexes who find, often too late, that their qualifications only fit them for one career: that of swelling the ranks of the already overcrowded and underpaid teaching profession. The production of a certain number of schoolmasters is a necessary element in the educational system of every country, but the question is: should this or the advancement of higher learning be the main function of a university endowed with public funds?

Many provincial colleges plead poverty as an excuse for overburdening their staffs with pedagogic and tutorial work. But these colleges are not too poor to vie with each other in the award of small scholarships, many of which go to pass students of no great ability. And experience, both in America and in this country, has shown that if only such objects as endowment of research are prominently brought before public notice, support will not be found wanting.

In conclusion, the directions where reform is most needed include the following:—

(1) Discontinuance of matriculation preparation—work which naturally belongs to the province of schools and crammers.

(2) Recognition of research work rather than tutorial instruction of pass candidates as the main duty of a professor outside his class-room.

(3) Reduction of the hours of class work, both of teachers and students.

(4) Revision of the now precarious conditions under which provincial appointments are tenable.

(5) Attraction of public attention to the importance of providing facilities for professorial research.

(6) The appointment of more and better paid assistant-lecturers and demonstrators.

(7) A more judicious expenditure of scholarship money, which should be restricted to honours students.

If the new university systems of this country are not, in the course of a few years, to take a subordinate position, and their degrees to sink into disrepute, if, in short, we are not to be left in the lurch by our foreign rivals, it becomes the duty of all who are responsible for the management of our provincial colleges and universities to have their attention aroused to a state of affairs which too often results in their professors being sweated and their students crammed.

## GOVERNMENT GRANT IN AID OF ANTARCTIC EXPLORATION.

THE following letter, referring to a Parliamentary grant in aid of Antarctic exploration, has been received by Lord Lister from H.M. Treasury, and sent to us by the Secretaries of the Royal Society:—

*Treasury Chambers, July* 3, 1899.

MY LORD,—I am directed by the Lords Commissioners of Her Majesty's Treasury to inform you that the First Lord has laid before the Board the memorial signed by your Lordship as President of the Royal Society, by the President of the Royal Geographical Society, and by other distinguished representatives of various branches of science, by which memorial application is made for a Government grant in aid of the expedition now being organised by the Royal Society and the Royal Geographical Society for the exploration of the Antarctic regions. This application has received the careful consideration of Her Majesty's Government, and I am directed to inform you that they are prepared to ask Parliament for grants amounting, in all, to 45,000*l.* towards the expenses of the proposed expedition, provided you are able to assure them that not less than an equal amount will be forthcoming from other sources, so as to enable the scheme to be efficiently carried out.

In making this announcement, I am to call attention to the latter part of the speech of the First Lord to the deputation which waited on him on this subject, as indicating that Her Majesty's Government must not be regarded, in making this promise, as inaugurating a new era of more extensive grants than formerly from the Exchequer in aid of scientific enterprises. Rather, it is to be understood that the very exceptional importance of the present scheme, so strongly represented by the deputation, is being recognised by the promise of a special grant.

At the present time, it is only necessary to add that the applications to Parliament for instalments of the grant will be spread over four years, of which 1900–1901 will be the first.

I am to ask you to be so good as to communicate this decision to the other signatories of the memorial.

I am, My Lord,
(Signed) FRANCIS MOWATT.

LORD LISTER,
President of the Royal Society,
Burlington House.

## NOTES.

THE Paris Academy of Sciences has been authorised to increase its number of national and foreign Correspondants from 100 to 116.

THE *British Medical Journal* announces that Sir John Burdon Sanderson, Bart., and Prof. Michael Foster, K.C.B., will be entertained at dinner by British physiologists on July 20, to congratulate them on the honours recently conferred on them by the Queen. The dinner will take place at the "Star and Garter," Richmond.

THE Volta Centenary Exhibition at Como, described in NATURE of June 22, has been completely destroyed by a fire, attributed to the fusing of some electric wires. Practically all the precious Volta relics were lost in the flames, notwithstanding the precaution taken to preserve the objects by placing them in a receptacle of solid masonry. The only things saved were a sword of honour presented by Napoleon the First to Volta, a picture by Bertini of Volta explaining his battery to Napoleon, a cast of the great electrician's skull, his watch, and a few personal relics. Volta's books and manuscripts, some of which were recently bought by the Italian Government for 100,000 lire, his collection of batteries, the only authentic portrait of Volta, his will, &c., were all destroyed. In spite of the destruction of the Exhibition, the committee has decided that the *fêtes* in honour of Volta shall be continued. The International Congress of Electricians will be held as previously arranged.

PROF. EWART exhibited a number of his zebra hybrids, their dams, sire, and half-brothers and sisters, at the great Agricultural Show recently held in Edinburgh. The authorities were little prepared for the interest taken in the exhibit, with the result that many thousands either failed to see anything of the hybrids, or had but a passing glance. The Prince of Wales, accompanied by a deputation of the Royal Agricultural Society of England, made a special inspection of the mixed family. From a contemporary we learn the Prince was so greatly interested that he requested Prof. Ewart to make a similar exhibition next summer at the Royal Agricultural Societies' Show at York. Should breeders give up empirical in favour of scientific methods, not a

little of the credit will be due to the Prince of Wales recognising the importance of the investigations that have for some years been carried on by the Edinburgh Professor of Natural History.

AN international conference organised by the Royal Horticultural Society for the purpose of discussing "Hybridisation (the cross-breeding of species) and the cross-breeding of varieties" was opened on Tuesday. In opening the proceedings, Dr. Maxwell Masters gave an address on the history of the subject. Papers dealing with the experimental production of plant-hybrids and the scientific significance of the results were read by Mr. W. Bateson, F.R.S., Prof. H. de Vries, Prof. George Henslow, Prof. L. H. Bailey, and Mr. C. C. Hurst.

*Science* announces that Dr. Milton Updegraff, professor of astronomy in Missouri University, has been appointed, by President McKinley, professor of mathematics in the United States Naval Observatory.

WE learn from the Secretary of the Institution of Electrical Engineers that the reunion of the Institution in Switzerland, from September 1 to 10 next, is likely to be well attended, and that the final arrangements for the visit are now in progress. It is hoped that a circular giving further details may be issued at the end of the current month.

To commemorate the services which the late Mr. H. T. Soppitt rendered to mycological science and to Yorkshire natural history generally, efforts are being made to obtain funds to form a Soppitt memorial library of mycological literature, of which the nucleus should be Mr. Soppitt's own books and herbaria, which the widow and family are willing to part with for such a purpose. Such further funds subscribed as are not required for the purchase of these, are to be laid out in the purchase of mycological reference-books. The library when formed will be presented to the Yorkshire Naturalists' Union.

MR. H. H. HOWELL, who joined the Geological Survey under De la Beche in 1850, retires from the service to-day. Mr. Howell, after surveying some portions of Wales and the south of Scotland, and large areas in the midland counties of England, became District Surveyor of the north-eastern counties of England in 1872, he was appointed Director for Scotland in 1882 (when Sir Archibald Geikie became Director General), and he was further promoted to be Director for Great Britain in 1888.

MR. ERNEST E. L. DIXON, who has for the past two years acted as assistant to Prof. Judd at the Royal College of Science, has been appointed an Assistant Geologist on the Geological Survey of England.

THE annual meeting of the Society of Chemical Industry commenced yesterday at Newcastle-upon-Tyne. In his presidential address, Mr. George Beilby dealt with the question of fuel and smoke. The magnitude of this problem may be judged from the fact that the total coal consumed in the United Kingdom in 1898 was 157 million tons, of which 76 million tons were consumed for the production of power for industrial purposes, 46 million for the production of heat for industrial purposes, and 35 million for the production of heat for domestic purposes. The various remedies which have been suggested to reduce this consumption by using coal more economically are (1) improved appliances for the combustion of raw coal, and distribution of the air supply in furnaces; (2) the transformation of the raw coal into smokeless fuel by preliminary treatment, either by destructive distillation in gas retorts or in coke ovens, or by its conversion into fuel gas by partial combustion in air and steam. Mr. Beilby considered these remedies, and concluded by suggesting that, as a means of bringing all of the different interests which are concerned in this matter into line, the Society should arrange for the holding of a conference on the subject of fuel and smoke, at which the leading technical societies, as well as the actual industries concerned, should be fully represented.—Prof. C. F. Chandler, of New York, was elected president of the Society in succession to Mr. Beilby.

THE death is announced of Sir Alexander Armstrong, K.C.B., author of "A personal narrative of the discovery of the North-West passage" (1857) and "Observations on Naval Hygiene, particularly in connection with Polar service," at the age of eighty-one. From the *Times* we learn that in 1849 the deceased was appointed surgeon and naturalist to Her Majesty's ship *Investigator*, under the command of Captain (afterwards Sir Robert) McClure, which sailed from Plymouth on January 20, 1850, for the Polar Sea in search of Sir John Franklin. After encountering many difficulties, the *Investigator*, in September 1851, was forced into a bay which Captain McClure named Mery Bay. Here both officers and men suffered great hardship and privation, the food being reduced during the second winter to two-thirds of its original quantity, and the sickness increasing to a great extent, when they were rescued from their perilous position hy Lieut. Bedford Pim. In the previous April, Captain McClure had taken a party from the ship and, crossing the strait, reached Melville Island, where he left notice in a cairn that the *Investigator* was icebound off Bank's Island. This notice was discovered by a travelling party from Her Majesty's ship *Resolute*, under Captain Kellett, who were stationed off Melville for their winter quarters. It was then that Lieut. Pim volunteered to go in search of the ship, which he reached on April 6, 1853, after a journey of 160 miles, which occupied him twenty-eight days. The *Investigator* was then abandoned, and the officers and crew were transferred to the *Resolute*; but, owing to that vessel being unable to get to the eastward, they were compelled to pass another winter—the fourth—in the ice. Eventually they were transferred to the *North Star*, and reached England on September 28, 1854. By this expedition the existence of a north-west passage was fully established. Sir Alexander Armstrong was appointed Director-General of the Medical Department of the Navy in 1869, and retired from that office in 1880.

AN account of some simple experiments on the best forms of curves for use with gliding or soaring machines for artificial flight has been sent to us by Mr. A. A. Merrill, of the Boston Aeronautical Society, U.S.A. A bicycle wheel was arranged to revolve in a vertical plane upon an axle fastened in a pier. From a point on the wheel a rod projected, and at the end of the rod the surface to be experimented upon was fixed at an observed angle with the plane of revolution of the wheel. The wheel was then started by the fall of a weight joined to the wheel in such a way that when the weight had fallen through a certain distance it became disconnected. After a surface had been fastened to the rod, the wheel was started, and when it had stopped the number of revolutions it had made was shown by a mechanical recorder. Given the same starting force, the number of revolutions would evidently depend upon the facility with which the surface moved through the air. The surface which offered the least resistance to motion was thus obtained. Among other results, the experiments seem to confirm Mr. L. Hargrave's statement that the existence of a wind vortex under a bird's wing is an important factor in soaring.

A SATISFACTORY report of the committee of the Albany Museum, Cape of Good Hope, for the year 1898, has been issued. While special attention has been given to the development of the South African collections, a number of specimens

of general interest have been acquired from foreign countries. Dr. S. Schönland, director of the museum, reports that the kitchen-middens near Port Alfred have again yielded a number of interesting specimens. Amongst them were portions of skulls of some human beings (which still await a careful examination) and a number of animal bones, amongst which was the lower jaw of the Vlakke Vark (*Phacochaerus aethiopicus*). This animal is quite extinct in Cape Colony now, and it was not previously known that it had occurred at all in that neighbourhood. Dr. Schönland has been able to get some light thrown on a question concerning the pottery found in these middens, which has hitherto puzzled many ethnologists. More or less large pieces of pottery, with holes neatly drilled through them, have frequently been found; and the meaning of these holes has hitherto been unexplained. It now appears that these pots with holes were used as miniature kilns, technically known as "saggers" (in which smaller pots were burned), and the need of holes through them becomes obvious when the use of these pots is known.

IN his introductory lecture, Prof. J. A. Thomson, the newly-appointed Regius Professor of Natural History in the University of Aberdeen, gives utterance to a note of warning as to the direction in which our biological studies are tending. "Amid the undoubted and surely legitimate fascinations of dissection and osteology, of section-cutting and histology, of physiological chemistry and physiological physics, of embryology and fossil-hunting, and the like, do we not need to be reminded sometimes that the chief end of our study is a better understanding of living creatures in their natural surroundings?" He even goes so far as to say that it is difficult to see any reason for adding aimlessly to the already overwhelming mass of morphological and systematic detail. And that what we should rather aim at is the understanding of the chief laws of organic architecture, of the certainties and possibilities of blood-relationship among living creatures, and a true conception of what is meant by the term organisation. As has been pointed out elsewhere by Prof. Alfred Newton, such a warning is undoubtedly needed at the present day, when there is far too great a tendency to regard the description of mere structure as the ultimate end of biological research. It is as if some person to whom modern telegraphy were unknown were to describe in great detail the mechanics of the various instruments employed therein without the vaguest conception of their practical use.

THE inexplicable habit of snails occasionally abandoning their shells is again alluded to in the July number of the *Journal of Conchology*. A former instance recorded was that of pond-snails (*Limnea*), but this time it is land-snails (*Helix*) captured at Venice. Here is a case in point illustrative of what is said above—the fact is all very well in its way, but is of no real interest unless we know the reason for such a strange perversity of habit.

THE most generally interesting article in the June number of the *American Naturalist* is one by Prof. Sylvester Judd on the efficiency of some of the protective adaptations of insects in securing their safety from foes. As the conclusions are chiefly based upon the undigested contents of the stomachs of a very large number of birds, it will be obvious that the author has a definite set of facts with which to test the validity of theories—and the facts are by no means always in accord with the theories. Especially is this the case with insects presenting a presumed protective resemblance with the object or ground on which they rest. Grasshoppers, for instance, even when lying still and then most like their surroundings, are snapped up by numbers of birds; as are also the larvæ of "looper" moths which resemble twigs, and likewise weevils. On the other hand, hairs, like those of many caterpillars, and, to a minor extent, the stings of bees and wasps, appear to be much more efficacious for protection. The brilliant colours of lady-birds seem likewise highly protective. "Warning colours" are, however, by no means always effective in this respect; and pungent odours and acid juices (which may be more suited to avian than to human palates) often also fail to save the insects in which they occur.

THE detailed studies that are now being made of the religious ceremonies of various native tribes of North America by trained American anthropologists are worthy of special study by all students of Comparative Religion. It is now possible, as Dr. J. Walter Fewkes points out in his account of "The winter solstice altars at Hano Pueblo" (*American Anthropologist*, n.s., i. p. 251), to trace the effect of one cult upon another in mixed populations. Walpi, for example, commenced as a settlement of Snake clans which had united first with the Bear phratry and subsequently with other phratries of lesser importance. The purport of the winter solstice (*Tuñtai*) rites at Hano is to draw back the sun in its southern declination and to fertilise the corn and other seeds, and to increase all worldly possessions. As at Walpi, strings with attached feathers are made and given to men and women with wishes that the gods may bring them blessings. These strings are also attached to beams of houses, placed in springs of water, tied to tails of horses, burros, sheep, dogs, chickens, and indeed every possession which the Indian has and wishes to increase.

THE experimental psychologists have passed from testing senses to experimenting on sensations, and "The Emotion of Joy" forms the subject of a monograph, by Dr. G. Van Ness Dearborn, in *The Psychological Review*, vol. ii., 1899. The first series of experiments consisted in recording what the subject said he felt like doing, or would probably do under the accession of hypothetical gifts of ten, one hundred, one thousand, ten thousand and one hundred thousand dollars respectively. The more practical experiments consisted in noting unconscious muscular movements during pleasant or unpleasant conditions of sound, light, smell, &c. It was found that somewhat in proportion to its proper pleasantness, an emotional extramotion consists in expansiveness and outwardly in contraction of extensor muscles; this is true of the smile and laugh of joy. Contraction of the extensor muscles is more pleasant in itself than contraction flexors; there is a general tendency to flexion under a (naturally unpleasant) sudden shock.

IN recent years several authors have published expositions of the methods originated by Hansen in dynamical astronomy; the text-books on lunar theory chiefly used in this country—Brown's "Lunar Theory," and the third volume of Tisserand's "Mécanique Céleste"—each devote a chapter to the subject. As the ephemerides of the moon given in the *Nautical Almanac* and the *Connaissance des Temps* are still calculated from Hansen's tables, as corrected by Newcomb, the theory cannot be neglected by astronomers; though in the hopes of mathematicians it has been somewhat displaced by the more fascinating work of living writers. In a memoir (*Ueber die Differentialgleichungen der Mondbewegung*), reprinted from the *Transactions* of the Leipzig Academy, Dr. Scheibner (who we believe is a former pupil of Hansen) develops systematically the numerous and complicated equations which form the basis of Hansen's theory of the moon's motion. The memoir will doubtless be welcome to those German students who have felt the need of something in their own language intermediate in character between the brief account given in Herz's article in the "Handwörterbuch der Astronomie," and Hansen's own exposition in the *Darlegung*.

"SOME Glacial Wash-plains of Southern New England" is the title of an essay by Mr. J. B. Woodworth (*Bulletin* of the

Essex Institute, Salem, vol. xxix.). These "wash-plains" or stream deltas and fans constitute a very important feature in the Pleistocene deposits of the region. They form the lowlands on which the greater number of towns and villages are built. To the early settler, they offered flat ground free from the boulders which are strewn over the uplands; and they yield vast stores of gravel and sand in fairly definite positions. Representing the morainal deposits of a retreating ice-lobe, they comprise the materials spread out at successive stages by streams and rivers which issued from the ice; and these deposits vary according to their original relations to the frozen mass. Hence the coarse gravels and the finest sands may be looked for in particular areas. No definite relations to sea-level are found among the various wash-plains. It is noticed that temporary lakes were at times produced by the local presence of blocks of ice; and it is pointed out that the retreat of the ice from the area was so recent that the general form of the deposits and most of their details remain unaltered. Owing, however, to the decay of some of the basaltic and other stones, the surface of the ground has been somewhat lowered.

HERR A. WEIGEL, of Leipzig, has acquired the last two remaining copies of Kützing's *Tabulae Phycologicae*, in 19 vols., with 1900 coloured plates, which he offers for sale at 2400 m. (Kützing's own copy) and 2000 m. respectively.

MESSRS. DULAU AND CO., of Soho Square, have issued a catalogue of botanical works, consisting entirely of works on Phanerogamia, which are arranged alphabetically in their natural orders. The same firm forwards also a catalogue of books and papers on British botany.

*Bulletin* 168 of the Cornell University Agricultural Experiment Station is devoted to an account, by Prof. G. F. Atkinson, of three species of Fungi which he regards as valuable from an esculent point of view, *Coprinus comatus*, *C. atramentarius*, and *C. micaceus*, with abundant illustratious.

DR. F. SCHLEICHERT has an interesting note, in a recent number of the *Naturwissenschaftliche Wochenschrift* (June 25) on the observation of phenomena of vegetable physiology in the winter. Many of them, especially those connected with the supply of nutrition, may be followed nearly equally well at that period of the year as in summer.

DR. L. O. HOWARD has published an account of the principal insects affecting the tobacco-plant in America in the *Year-book* of the Department of Agriculture for 1898. Although the plant is said to have no enemies peculiar to itself, it suffers from the attacks of many omnivorous *Lepidoptera*, especially Sphinges and Noctuæ; and from those of various *Coleoptera*, *Hemiptera*, &c.

WE have received parts 10-12 (published in 1898) of the second volume of a journal called *Lavoura*, published by the National Society of Agriculture of Brazil. Among the miscellaneous contents which fill the magazine, we find a coloured plate of the imago and pupa of a butterfly (*Heliconius eucrate*, Hübn.); illustrated articles on a formidable internal parasite (*Anchylostoma*), and on the history of the wheat-plant; a portrait of the late Prof. Aimé Girard; notices and figures of *Eleusina coracano* and *indica* (forage-plants); and much agricultural and statistical information, primarily, of course, of local interest.

THE first number of *Le Mois scientifique et industriel*—a monthly synopsis of scientific information—has been received. To some extent, the new periodical resembles *Science Abstracts*, but it contains more abstracts of engineering papers, and less of scientific investigations. The abstracts are concise, comprehensive as regards nationality, and well printed; they should, therefore, be of real service to French readers interested in the progress of pure and applied science.

A CAREFUL investigation of tautomeric compounds, *i.e.* substances which react as though each possessed more than one molecular structure, though only represented by *one* substance, has revealed in a few cases the actual existence of the different structural forms. A very interesting example is furnished by diacetylsuccinic ester, which has lately been studied by Prof. Knorr. At the time of its discovery it was regarded as a single distinct individual, having the formula

$$\begin{array}{ccc} CH_3.CO.CH & . & CH.CO.CH_3 \\ | & & | \\ COOR & & COOR \end{array}.$$

According to Knorr the presence of the other structural isomers has been overlooked from the fact that, though not the most stable relatively, the original compound has the highest melting point, and, being the least soluble, has crystallised most readily from solution. Knorr predicted some time ago the existence of seven isomeric compounds, not including optically active forms, and of these he has already succeeded in preparing five, whilst he considers it very probable that the two missing members will be found. These will be represented by the following formulæ:—

$$\begin{array}{cc} CH_3.CO.CH.COOR & CH_3.C(OH):C.COOR \\ | & | \\ CH_3.CO.CH.COOR & CH_3.C(OH):C.COOR \\ \text{Keto-form} & \text{Enol-form} \\ \text{representing two} & \text{representing three} \\ \text{inactive forms.} & \text{cis-trans-forms.} \end{array}$$

$$\begin{array}{c} CH_3.C(OH):C.COOR \\ | \\ CH_3.CO.CH.COOR \\ \text{Keto-enol-form} \\ \text{representing two} \\ \text{inactive forms.} \end{array}$$

A RECENT issue of the *Transactions* of the Oxford University Junior Scientific Club contains a valuable account, by Mr. A. F. Walden, of the condition of dissolved substances in solutions other than aqueous. The experiments of Carrara have shown that solutions in methyl alcohol exhibit a progressive ionisation, and that the independence of the ions is as clearly marked as in the case of aqueous solutions. Tessarin has also shown that the molecular lowering of the freezing point of formic acid brought about by the chlorides and bromides of the alkali metals is abnormally high, showing that this solvent also behaves like water. Recent experiments by Franklin and Kraus have shown that liquid ammonia acts as a dissociating solvent. In reference to the hypothesis of Nernst that the dissociating influence of a solvent is related to its dielectric capacity, it is to be remarked that the dielectric constants of water, methyl alcohol, acetone, formic acid, and ammonia are all high. It is pointed out also that these solvents, with the possible exception of acetone, are characterised by having "associated" molecules. On the whole, therefore, it may be said that the phenomena which it is attempted to represent by the hypothesis of electrolytic dissociation are not peculiar to aqueous solutions. They are, so far as experimental evidence is available, found to be characteristic of solutions of salts in other solvents possessing high dielectric capacities and complex or associated liquid molecules. According to Thwing, the dielectric capacity is both an additive and a constitutive property. It increases as the temperature is lowered. The factor of association, according to Ramsay and Shields, also increases as the temperature is lowered. These facts have all to be considered in dealing with solutions and in comparing ionisation determinations made by different methods. Thus we have some explanation of the observation that the degree of ionisation of metallic salts dissolved in methyl or ethyl alcohol is uniformly less when estimated by the boiling point method

than when measured by the determination of electrical conductivity at a lower temperature.

THE additions to the Zoological Society's Gardens during the past week include a Macaque Monkey (*Macacus cynomolgus*) from India, presented by Mr. J. H. Higgins; two Maholi Galagos (*Galago maholi*) from South Africa, presented by the Hon. Gilbert Johnstone; two Common Badgers (*Meles taxus*), British, presented by Mr. A. Gorham; a Spring-bok (*Gazella euchore*, ♂), a Ring-hals Snake (*Sepedon haemachates*) from South Africa, four Spur-winged Geese (*Plectropterus gambensis*) from West Africa, presented by Mr. J. E. Matcham; two Lanner Falcons (*Falco lanarius*) European, presented by Sir H. H. Johnston, K.C.B.; a Yellow-fronted Amazon (*Chrysotis ochrocephala*) from Guiana, presented by Mrs. G. F. Cote; a Hunting Crow (*Cissa venatoria*) from India, a Black-necked Grackle (*Graculipica nigricollis*) from China, a Larger Rocket-tailed Drongo (*Dissemurus paradiseus*) from India, a Sacred Kingfisher (*Halcyon sancta*) from Australia, a Black Hangnest (*Cassidix orizivora*) from the Amazons, two Blackbirds (*Turdus merula*), European; a Brown Thrush (*Turdus leucomelas*) from South America, presented by Mr. Russell Humphreys; an Arabian Baboon (*Cynocephalus hamadryas*) from Arabia, three Barbary Partridges (*Caccabis petrosa*) from North Africa, three Western Pintailed Sand-Grouse (*Pterocles pyrenaica*), South European, a Grand Galago (*Galago crassicaudata*) from East Africa, three Black-headed Terrapins (*Damonia reevesi-unicolor*), three Reeve's Terrapins (*Damonia reevesi*) from China, a Home's Cinixys (*Cinixys homeana*), a Derbian Sternothere (*Sternothaerus derbianus*) from West Africa, three Reticulated Pythons (*Python reticulatus*) from the East Indies, deposited; four Crested Pigeons (*Ocyphaps lophotes*) from Australia, an Ostrich (*Struthio camelus*, ♂) from Senegal, a Sun Bittern (*Eurypyga helias*) from South America, a Scarlet Ibis (*Eudocimus ruber*) from Pará, purchased; a Japanese Deer (*Cervus sika*, ♂), born in the Gardens.

The comet is still on the borders of Sagittarius and Capricornus, about 3° west of α and β Capricorni. M. L. Schulhoff points out in *Ast. Nach.* (No. 3574) that it is important to secure as many accurate observations of the comet as possible at observatories of different latitudes during this apparition, as by this means our knowledge of the mass of Jupiter may be considerably improved.

THE NEW ALLEGHENY OBSERVATORY.—A little over a year ago Mr. J. A. Brashear inaugurated a movement to provide for the erection of a new building and an adequate instrumental equipment for the Allegheny Observatory, and the fund, from numerous subscriptions received, has grown to such proportions that the plan shows every sign of success. Prof. F. L. O. Wadsworth, until recently a member of the staff of the Yerkes Observatory, has been appointed to the directorship, and the plans for the new building have been prepared by him. The largest instrument is to be a refracting telescope of 30 inches aperture, with object-glass by Brashear, and special provision is to be made for astrophysical investigations, which will form the principal work of the observatory.

LEEDS ASTRONOMICAL SOCIETY.—The *Journal and Transactions* for the year 1898, lately issued, maintains the excellent standard of former years. Among the many interesting papers mention may be made of "The movements of the moon," "Star temples in Egypt," "Astronomy as applied to navigation." The volume contains two plates, one showing four drawings of Jupiter and one of Saturn made by Mr. H. J. Townshend, and the other a portrait of Mr. T. J. Moore, who has charge of one of the micrometers from the Oxford Observatory, with which he is engaged in measuring the plates for the Astrographic Catalogue. Accompanying this is a very lucid description of the work and scope of the Astrographic Survey, by Mr. Moore.

## *THEORY OF THE MOTION OF THE MOON.*[1]

THE second part of Dr. Brown's "Lunar Theory" contains the calculation of the terms of the third order in the eccentricities, inclination and ratio of the parallaxes. The first part (reviewed in NATURE, November 25, 1897) had already dealt with the general theory, the variation, and the terms of the first and second orders. It will be remembered that the differential equations to be solved are

$$(D+m)^2u+\tfrac{1}{2}m^2u+\tfrac{3}{2}m^2s-\frac{ku}{(us+z^2)^{\frac{3}{2}}}=-\frac{\partial\Omega_1}{\partial s}$$

$$(D-m)^2s+\tfrac{1}{2}m^2s+\tfrac{3}{2}m^2u-\frac{ks}{(us+z^2)^{\frac{3}{2}}}=-\frac{\partial\Omega_1}{\partial u}$$

$$(D^2-m^2)z-\frac{kz}{(us+z^2)^{\frac{3}{2}}}=-\tfrac{1}{2}\frac{\partial\Omega_1}{\partial z}.$$

The notation is sufficiently familiar to render explanation unnecessary.

Dr. Brown's procedure is as follows:—Let

$$u=u_0+u_\mu+u_\lambda,\ z=z_\mu+z_\lambda$$

where $u_0$ denotes the variational terms

$$u_\mu,\ z_\mu$$

the terms of the orders already calculated

$$u_\lambda,\ z_\lambda$$

the terms of the next order to be calculated.

Then expanding by Taylor's theorem the unknown terms enter in the form

$$\zeta^{-1}(D+m)^2u_\lambda+M\zeta^{-1}u_\lambda+N\zeta s_\lambda,$$

and

$$D^2z_\lambda-2Mz_\lambda,$$

M, N being functions of the known variational terms.

The unknown terms enter under the same form every time, but if a solution with indeterminate coefficients be assumed, the coefficients in the simultaneous equations that result will depend upon the period of the inequality under consideration, and therefore, from the point of view of numerical solution, entirely different nearly every time. All who have had the practical

[1] "Theory of the Motion of the Moon; containing a New Calculation of the Expressions for the Coordinates of the Moon in Terms of the Time." By Ernest W. Brown, M.A., Sc.D., F.R.S. (from the *Memoirs* of the Royal Astronomical Society, vol. liii.).

experience know how laborious is the solution of twenty simultaneous equations. Prof. Brown estimates the solution of the equations at half the labour of obtaining them, in addition

to the fact that this portion of the work is peculiarly liable to numerical error. He may therefore be congratulated on having obtained an algebraical solution, reducing the operation of finding fresh terms to mere multiplication of series. The mathematical investigation is referred to as destined for publication elsewhere, and does not appear in the memoir. The underlying principle is that when in a differential equation of the $n$th order there are $n-1$ integrals known, when the right-hand member of the equation is zero, then a particular integral in the general case can be obtained. In the lunar theory the differential equation is, in effect, of the fourth order, and three integrals are known, two representing the elliptic inequality and the third a variation of the epoch.

For forming the right-hand sides of later stages, the quotient of each set of terms by the variation terms is required. As divisions are troublesome, these quotients are the quantities sought in the first instance: the new set of terms can then be obtained by a multiplication. The quotients referred to are given algebraically as the sum of four products, each product being that of two series. It is inconvenient, in the numerical application of the above method, that small coefficients often appear as differences of comparatively large numbers. Dr. Brown gives as an example a case where a coefficient 2 arises as the sum of separate coefficients

$$-6418+6496+316-392$$

from the above-mentioned four products.

Terms of long period require a special treatment, but the general methods apply to the other terms of the group. The loss of accuracy is reduced to that due to the first, instead of the second, order of the small divisor.

When the period is that of the elliptic inequality, a new part of the motion of the perigee has to be determined. Calling this new part $c_{\lambda/e}$ a new unknown term $\zeta^{-1}(\mathrm{D}+m).u_e c_{\lambda/e}$ appears, and is transposed to the right-hand side of the equation, so that the quantities A, which in other cases are completely known, now appear in the form $\mathrm{B}+c_{\lambda/e}b$, where B, $b$ are known. Dr. Brown has already shown in the first part how $c_{\lambda/e}$ may be obtained before the coefficients of the inequalities are calculated. When this has been done, one of the equations becomes redundant. Another is already redundant, until the meaning of the arbitrary constant denoting the ellipticity is defined with further precision. Dr. Brown defines the arbitrary constant so that $\epsilon_0-\epsilon_0'=1$ to all orders; hence $\lambda_0=\lambda_0'$. The other coefficients $\lambda_\iota$, $\lambda_\iota'$ consist of three parts, one proportional to $c_{\lambda/e}$, and arising from the quantities $b$, a second arising from the quantities B, and a third proportional to $\lambda_0$. The two equations for which $\iota=0$ then give a double determination of $\lambda_0$, and furnish a check upon the numerical accuracy. Many of the quantities that occur in this arrangement of the computations are of service at subsequent stages.

The treatment of the third coordinate follows the same lines, and only differs in being more simple.

The foregoing table exhibits the extent of the calculations already performed, and the results of the first part are for convenience included in it.

The decrease of accuracy of the terms in the twenty-second and twenty-third groups is due to the period of one term approximating to the synodic period. Even in these cases, the coefficients are given to less than one-thousandth part of the least quantity that could be detected by observation.

P. H. C.

## *INVESTIGATIONS OF DOUBLE CURRENTS IN THE BOSPHORUS AND ELSEWHERE.*[1]

AS my books and papers are published chiefly in the Russian language, they are not very well known in this country. A short account of some of my results may therefore not be without interest. I cannot, in the course of my address, make you familiar with all my works, and wish at the present moment only to draw your attention to the interesting phenomena of double currents in the Straits of Bosphorus, Gibraltar, Bab-el-Mandeb, Formosa, and La Pérouse.

The Strait of Bosphorus joins the Black Sea and the Marmora Sea. The Black Sea water has in it—roughly speaking—half the quantity of salt found in the water of the Mediterranean.

[1] Abridged from a paper by Vice-Admiral S. Makaroff in the *Proceedings* of the Royal Society of Edinburgh (vol. xxii. No. 4, 1899).

The water of the lower strata of the Marmora Sea has the same composition as the water of the Mediterranean. The upper strata, say from ten fathoms upwards, contain water of intermediate salinity between the water of the Mediterranean and the water of the Black Sea. This difference in the salinity of the water is the chief reason of the enormous double current of the Bosphorus. Let us imagine that at a certain given moment the level of both seas is at the same height. The pressure of the column of water in the Marmora Sea will be greater than that in the Black Sea; the difference would increase with the depth, and it would disappear at the surface. For this reason, the water in the lower strata of the Marmora Sea rushes into the Black Sea, keeping close to the bottom. That rush of water after a certain time will raise the level of the Black Sea, producing a difference in the level of the two seas, which causes a superficial current to flow out of the Black Sea in the opposite direction to the under current. Here we see distinctly that the principal reason for the double current is the difference in the salinity of the water, and should that difference in salinity cease the double current would be discontinued. The fact is that in the Black Sea evaporation does not exceed the quantity of water supplied by rains and streams, and this excess of fresh water maintains the difference of salinity in the waters of the Black Sea and Mediterranean.

The existence of double currents in the Bosphorus was known long ago, and Marsilli in 1681, in his letter to Queen Christina of Sweden, has described them. Later they were somehow forgotten, and some interesting papers have been published, in which the authors try to prove that the double current was legendary. Rear-Admiral Sir W. J. L. Wharton (who is now at the head of the Hydrographic Office) was the first to show by direct observations that a double current existed in the Bosphorus. I was there a few years after him, commanding the stationary steamer *Taman*. I began to take observations of the specific gravity of the water at different depths, and I found out that the water forming the lower strata contained twice as much salt as the water of the upper strata; after this, a double current was quite evident to me.

I do not wish to detain you with an account of the different results referring to the velocity of both currents, and will only point out to you that the lower current is similar in many details to an ordinary river, while, on the contrary, the upper current differs much from an ordinary river, probably for the reason that, while the surface of it is falling gradually down, the bottom rises constantly.

The difference of level of the Black Sea and Marmora Sea, calculated from the difference in the specific gravity of the water, I found for the month of July 1882 to be 1·396 feet.

In the Strait of Gibraltar I had only five stations, and made my observations one day only. I had no opportunity of measuring the velocity of the current, but the phenomenon is very similar to what I found in the Bosphorus. The water of the Atlantic rushes into the Mediterranean, the difference between the surface levels being, according to my calculations, 0·54 foot.

The evaporation of water from the Mediterranean is greater than the quantity supplied by rivers and rains. For this reason, the water becomes more dense, settles down, and goes back to the Atlantic by the under current.

I wish to point out here that the temperature of the lower strata of the Mediterranean coincides with the mean winter temperature of the air in the eastern part of the sea. This is quite evident, because in winter the temperature of the water to a great depth corresponds to the temperature of the air. In summer, the surface water is much warmer, but this high temperature cannot penetrate to a great depth. I am sorry that I have not time to discuss more fully this question, but in the Straits of Bab-el-Mandeb we have the same phenomena as in the Gibraltar Strait and Mediterranean. Here again—by my observations—the temperature of the lower water strata coincides with the winter temperature of the air at the place where the water settles down.

In the three straits already mentioned we have a double current: superficial and bottom current. In the Straits of Formosa and La Pérouse there are also two currents, but both are superficial.

I ought to mention that the influence of the rotation of the earth on the direction and velocity of the currents cannot be over-estimated. I shall not discuss this question fully, but the fact that in every salt inland sea there is a circular rotation of the water in a direction opposite to the apparent movement of the sun, shows that the rotation of the earth has very much to do with the direction of the currents. In the vicinity of islands, for the same reason, the water follows a direction coinciding with the apparent movement of the sun. It is for this reason also that the water alongside the Chinese coast flows to the south during the north-easterly monsoon as well as during the south-westerly monsoon. The Kuro-Siwo current going to the north and north-east cannot touch the Chinese coast because there is brackish water flowing to the south-west.

In the Strait of Formosa the specific gravity and temperature of the water at the Chinese coast are quite different from what is observed off the coast of Formosa. This difference in the temperature and specific gravity may give to a sailor a good guide for a fair passage through the Strait. The temperature of the water, say, in the month of February at the Chinese coast is 11° C., while at the coast of Formosa it is 20°. If the captain will try during the month of February to follow the line of the temperature of 15° he will pass at a good distance from the dangers of both coasts. Moreover, at the Chinese coast in winter it is possible to find water at less than 1·0240 $\left(S\frac{17·5}{17·5}\right)$, while at the coast of Formosa it is seldom less than 1·0265.

Every sailor knows how difficult is the passage through the Strait of Formosa. During the north-easterly monsoon the weather is very thick, and the depth of the sea cannot in these places be regarded as giving a good means for determining the position of the ship. It may happen that after a ship leaves, say, Nagasaki the captain never knows his position until he runs on the Chinese coast and wrecks his ship. My opinion is that a regular temperature service should be arranged from Turnabout Lighthouse; everyday a pilot boat should put to sea, taking temperatures both going out and returning, and the temperature of the water should be wired to all Chinese and Japanese ports for the information of the captains. By these means many ships would be saved from danger.

The currents in the Strait of La Pérouse are very complicated. There is a very narrow and long strip of cold water, which lies in the direction from N.W. to S.E.; a vessel crossing that strip in July may have temperatures of 18° C., then 5°, and again 16° or 18°. It would take me too long to explain the source from whence the cold water comes, and why it is constantly there; it is the cause of fogs which render navigation in that place very difficult. I may briefly say that the Kuro-Siwo current partly enters the Sea of Japan, and the excess of water escapes partly through the Strait of La Pérouse into the Okotsk Sea. Due to the rotation of the earth, the current turns to the south-east and flows alongside the Island of Yezo. This water is warm and dense, having much salt in it. The water of the Okotsk Sea—particularly in the vicinity of the Island of Saghalien—is in summer also pretty warm, but it is much lighter than the water of the Kuro-Siwo, and thus while the denser water sinks down, the lighter water tries to rise on the top of it. The difference of level which is produced hereby brings to the surface the cold water of the lower strata.

I studied this Strait in 1887 and 1888, and published the results of my study, but when I came to the Pacific again in 1895, as the Admiral commanding the squadron, I was very anxious to go to the Strait of La Pérouse to re-investigate the currents, and now I am in possession of very valuable material on this subject, which is almost ready for publication.

I do not propose to take up more of your time at present with particulars of these five straits. I only wish to remind you what important information the thermometer and hydrometer can give in the study of the different parts of our so little-known planet. You know better than I that studies in that direction ought to be continued, and no nation in the world has been so liberal as England, which found means to send out for four years the *Challenger* with a scientific staff to explore the deep sea. But it is not always possible to find such means, and it is advantageous to associate ordinary seamen with that kind of work.

I should be very glad if oceanographers would come to certain definite opinions with regard to the mode of collecting the information about the temperature of the surface water. It would be a great advantage to knowledge to divide the study of the sea with regard to the temperature. Suppose Russia should take Okotsk Sea, Bering Sea, or Sea of Japan, Black Sea, White Sea, Kara Sea, and the Finnish Gulf, England takes the Atlantic, United States takes Northern Pacific, Germany

takes Indian Ocean, France takes South Pacific, Sweden and Norway take North Sea, Baltic Sea and the Arctic Sea. Every nation should extract the information in regard to the temperature from ships' log books, put it in tables of approved description, and send it to the corresponding nation; this will give means to collect enormous information. The observations of every ship in a certain square ought to be placed on a separate card. Boxes containing these cards, say for the North Pacific, would not occupy more space than can be found in a good-sized book-case.

When a new journal of a ship is received, temperatures of sea water observed on board that ship should be placed on the cards, and the cards put in their corresponding place. In this way we should, each year, become richer in the knowledge of the temperature of the surface water, and no observation would be lost. Every observation would increase our knowledge of the temperature of sea water. It would be a real pleasure to see that progress of knowledge, and if ever this system or any other system be accepted, it will help us to study many details which, up to the present time, are unknown.

## *UNIVERSITY AND EDUCATIONAL INTELLIGENCE.*

MR. R. L. JACK, Government Geologist, Queensland, now on a visit to this country, is to receive the honorary degree of LL.D. of Glasgow University on July 20.

MR. E. A. MINCHIN, Fellow of Merton College, Oxford, has been elected to the Jodrell Professorship of Zoology in University College, London, in succession to Prof. W. F. R. Weldon.

THE Bill for establishing a Department of Agriculture and Technical Instruction in Ireland was read for a second time in the House of Commons on Thursday last, and referred to the Standing Committee on Trade.

FOR the purpose of encouraging the study of botany, the London Technical Education Board have had the botanical gardens in Battersea, Ravenscourt and Victoria Parks laid out upon an organised plan. Good collections of plants, representing various natural orders, have been obtained, and suitable arrangements have been made for the convenience of teachers and students. The more important trees and shrubs in the parks have been labelled, and lists have been supplied for insertion in the botanical guide which the Board proposes to issue shortly for the convenience of students. Teachers of botany can obtain tickets for themselves and pupils for admission to the botanical gardens at the Battersea, Ravenscourt and Victoria Parks by application to the Secretary of the Board.

BY the recent gifts of Mrs. Stanford (*Science* states), Leland Stanford Jr. University becomes the richest university in the world, far surpassing in its resources Harvard, Columbia, or any other university. The resources of the University consist of three great farms, aggregating 95,000 acres of land, deeded by Act of Legislature. On one of these farms, which constitutes the University Campus, buildings to the value of one million dollars were erected before Senator Stanford's death. By his will the University received 2,500,000 dollars in cash, invested in interest-bearing bonds. During the litigation following his death, Mrs. Stanford gave to the University (by deed) her own private fortune, amounting to about a million dollars. By her recent gift she transferred the residue of the estate to the University, it being necessary to do this by deed of gift under the laws of the State. The property just transferred has a commercial value—judging from the revenue stamps put upon the deeds—of 35,000,000 dollars. What its actual value may be only the future] can determine. The income arising from this final gift is at present relatively small, as by agreement among the railroads, in bonds and stock of which it largely consists, the earnings are for a time to be used in freeing the property from debt and in making improvements.

AT the annual dinner of the Old Students' Association of the Central Technical College, held on Thursday last, Prof. W. E. Ayrton, in proposing the toast of the Association, referred to the progress of the College and the insufficiency of accommodation due to the continued increase in the number of students. He announced that the electrical department would soon be greatly extended by the erection of a large new dynamo room nearly six times the size of that at present in use, and occupying a considerable part of the ground floor of the new building of the Royal School of Art Needlework adjoining the College. The accommodation for this department would be further increased by the completion of a new drawing office and a new lecture theatre. Sir Philip Magnus, in proposing the toast of the College and its professors, remarked that the College was that day entering on a new period in its career, for it was likely to become an integral part of the new University of London, which had decided the day before to move into new quarters at the Imperial Institute next door to the College. The needs of the College were recognised in the new University by the decision to appoint a faculty of engineering for the first time in the history of University education, and by the variation of the University matriculation examination to suit the requirements of different classes of students. Prof. Armstrong, in replying to the toast of the Chairman, alluded to the research work done at the College, especially in relation to its value as a means of mental training.

## *SCIENTIFIC SERIALS.*

*Bulletin of the Amerian Mathematical Society*, June.—Prof. F. N. Cole reports the April meeting of the Society held in New York City, and summarises the thirteen papers which were contributed. He also indicates where the papers themselves may be or will be found.—Surfaces of revolution in the theory of Lamé's products is a paper which was read by Dr. Safford at the February meeting. It is a review of an article by Haentzschel (reduction der Potentialgleichung), in which that writer criticises results obtained by Wangerin in the *Berliner Monatsberichte* (February 1878). Dr. Safford agrees with Wangerin in the results he gets, and so, in his opinion, invalidates Haentzschel's criticisms.—The next article is an enthusiastic review by Mr. Arthur Berry of Picard's "Théorie des Fonctions Algébriques de deux Variables indépendantes."—Another review is one of Jules Tannery's "Leçons d'Arithmétique théorique et pratique," by Prof. J. Pierpont. This latter is pronounced to be the first work on arithmetic which the reviewer has seen which, while intended entirely for secondary instruction, is written in accordance with the new ideas regarding the number concept and the need of rigour. Thus it is a pioneer of a revolution in secondary instruction.—Dr. L. E. Dickson contributes a note on Page's ordinary differential equations (*cf.* a review of this by Prof. Lovett in the *Bulletin*, April 1898).—The usual notes and new publications close the number.

IN the *Journal of the Royal Microscopical Society* for June, besides the usual summary of current researches in zoology, botany, and microscopy, is a further instalment of Mr. F. W. Millett's report of the recent Foraminifera of the Malay Archipelago; and an article by the president, Mr. E. M. Nelson, on the rackwork coarse adjustment, in which he traces the history of the application of rackwork to the focussing of the microscope from the time of Bonannus in 1691 down to the most recent improvements.

THE *Journal of Botany* for July contains an article, with illustrations, on a new British fresh-water alga, by Dr. A. B. Rendle and Mr. W. West, jun. The alga is a new species of the interesting genus *Pithophora*, first found by Wittrock in a tank in Kew Gardens. Like Wittrock's species, however, it has no claim to the title of "British" beyond the fact that it was found in a canal near Manchester, where it had unquestionably been introduced with cotton-bales. The remaining papers in both the June and the July numbers appeal to those interested in descriptive and geographical botany.

## *SOCIETIES AND ACADEMIES.*

### PARIS.

Academy of Sciences, July 3.—M. van Tieghem in the chair.—Considerations on the physical constitution of the moon, by MM. Lœwy and Puiseux. A summary of conclusions arrived at from recent photographic study of the moon. Certain

comparisons are drawn between the structure of the moon's surface and that of the earth, and evidence is adduced of the existence, at the present time, of a remnant of the original lunar atmosphere.—Examination of sea-water drawn from different depths: variation of iodine compounds therein, by M. Armand Gautier. Examination of water taken from the surface of the Mediterranean shows, as has been previously found to be the case with the Atlantic Ocean, the entire absence of iodides and iodates, the whole of the iodine present being contained partly in microscopic organisms and partly in combination with a complex organic substance which contains nitrogen and phosphorus, and is capable of dialysis. The total amount of iodine present is nearly the same for all depths, but the form in which it exists varies considerably. Thus, at the bottom of the sea iodine exists in the form of iodides and iodates to the extent of 0·305 milligramme per litre, and the quantity decreases with decreasing depth until it disappears altogether at the surface. On the other hand, the iodine contained in living organisms is greatest in amount at the surface, and gradually diminishes as the depth increases. The iodine present in the form of soluble organic compounds is much more constant in amount, the maximum quantity being found at a depth of 880 metres. The water of the Mediterranean appears to be somewhat poorer in iodine than that of the Atlantic, the total quantities found being 2·25 and 2·40 milligrammes per litre respectively.—Observations of Swift's comet (1899*a*) made with the Brunner equatorial at the Lyon Observatory, by M. J. Guillaume.—On the suppression of trial methods in the calculation of parabolic orbits, by M. L. Picart.—On the transformation of surfaces, by M. E. O. Lovett.—On the surfaces of Voss, by M. C. Guichard.—The groups of the order $16p$, $p$ being an odd prime, by M. Le Vavasseur.—On the development of a uniform branch of analytic functions in a series of polynomials, by M. Paul Painlevé.—On two integrable equations of the second order, by M. E. Goursat.—On a class of equations to partial derived functions, by M. Ivan Fredholm.—Considerations on the works of MM. S. Lie and A. Mayer, by M. N. Saltykow.—Wandering globular sparks, by M. Stéphane Leduc. When two fine metallic points are connected with the poles of an electrostatic machine, and placed in contact with the sensitive film of a photographic plate resting on a metal surface, an effluvium is produced around the positive point, and a luminous globule appears at the negative point. This globule increases in size, detaches itself from the negative, and slowly wanders towards the positive, point; on reaching the latter the luminosity ceases, and the machine is found to be discharged. The phenomenon suggests a comparison with globular lightning.—The frequency of nervous oscillations, by M. Auguste Charpentier.—On the nature and cause of the phenomenon of coherers, by M. Thomas Tommasina. An account of further experiments on the formation of conducting chains of metallic particles in coherers.—On the position of the points of magnetic transformation of nickel steels, by M. L. Dumas. The influence of chemical composition on the magnetic properties of steels is described and discussed.—On the volumetric estimation of zinc, by M. Pouget. In the new process here described the solution of zinc is treated with hydrogen sulphide and the precipitated zinc sulphide decomposed with a known amount of iodine solution, the excess of the latter being subsequently determined by titration with thiosulphate.—On the preparation and properties of the arsenides of strontium, barium, and lithium, by M. P. Lebeau. The arsenides of the metals in question were obtained by the reduction of the corresponding arsenates with carbon at the temperature of the electric furnace. They are reddish-brown substances presenting a crystalline fracture, and are rapidly decomposed by water with evolution of hydrogen arsenide and formation of the hydroxide of the metal.—A study of methylic oxymethylene-cyanacetate and some of its homologues, by M. E. Grégoire de Bollemont. Methylic, ethylic, and amylic oxymethylene-cyanacetates have been prepared from the corresponding ethereal salts, which have been previously described. These compounds exhibit the characteristics of strong monobasic acids, and may be looked upon as substitution derivatives of formic acid.—The use of tetrachlorohydroquinone for the characterisation and separation of fatty acids, by M. L. Bouveault. Tetrachlorohydroquinone reacts with one and two molecules of the chlorides of fatty acids to form stable, well-crystallised compounds which are easily purified, and thus eminently adapted for the identification, and in some cases for the separation, of the acids. The physical properties of some of these compounds are described.—On the presence in the animal organism of a soluble ferment which reduces nitrates, by MM. E. Abelous and E. Gérard. Experiments are described which show that the various organs of the body contain, in different proportions, a soluble substance of the nature of a ferment which reduces nitrates to nitrites. A temperature of 20–40° is most favourable to the reaction, which ceases altogether at 72°.—On the reducing power of urine, by M. Henri Hélier. The author determines the reducing power of urine by titration with potassium permanganate solution in the presence of sulphuric acid, the result being expressed with reference to urine of normal concentration, as measured by the amount of urea present. In many diseases, the reducing power is characteristically higher or lower than the normal.—Contribution to the study of the bark of *Rhamnus purshiana* (Cascara Sagrada), by M. Leprince. The presence is demonstrated of chrysarobin, chrysophanic acid, and emodine.—Direct transformation of acetamide into ethylamine by hydrogenation, by M Guerbet. The reduction is effected by means of metallic sodium in the presence of boiling amylic alcohol.—On the secretion of diastases, by M. Dienert.—Peculiarities of the eruption of Vesuvius, by M. Matteucci.

## PRESTWICH AND PRACTICAL GEOLOGY.

*Life and Letters of Sir Joseph Prestwich.* Written and edited by his Wife. Pp. xiv+444. (Edinburgh and London: Wm. Blackwood and Sons, 1899.)

THIS is a pleasantly written personal history of a well-known man, and as such interesting to his friends who survive him and to the numerous friends of his friends who have passed away but are spoken of in connection with him. Scientific inquiry, however, filled so large a part of his life, and he did so much for the elucidation of certain branches of geological inquiry, that the story cannot fail to be more or less an account of the progress of research along those lines to which he devoted himself.

Born of a good north-country stock, Prestwich was sent to school while very young, and although people took a fancy to the spirited boy and were kind to him, he must have had to rough it somewhat in childhood. At sixteen he entered at University College, London, where he worked hard and successfully, but confined his attention, unwisely as he allowed in after life, too much to chemistry and natural philosophy to the neglect of mathematics and classics.

Yet it must not be supposed that he was a one-sided man, for he carefully apportioned his time when it was more at his own disposal, and went through a very full if not severe training. His extensive reading in English literature and his knowledge of the French language, acquired when a boy at school in France, and kept up in after life, proved of the greatest assistance to him. Joseph Prestwich, jun., was soon well known in the scientific world, and those social qualities and that genial temperament which made "Uncle Jovis' parties" so delightful to the happy children he loved to gather round him, enabled him also to do much to further the co-operation of scientific workers, and "Prestwich's Easter excursions" were not less highly appreciated by the geologists who had the privilege of joining them.

These excursions were certainly very pleasant and profitable. They were thoughtfully planned and well-managed. The party, generally consisting of one carriage load, met at some appointed spot. A few put their heads together when invited by the leader to do so, details were arranged, orders as to hours were given—these often involving a very early start—a call all round for say 10*l.*, which was carefully administered till spent, when a new call was made, then from each halting-place visits to points of interest, examination, discussion, demonstration, and home to dinner.

Among the illustrations in the book are excellent portraits of some of his more intimate friends, most of whom at one time or another accompanied him on his geological excursions.

He had for forty years to give most of his time and attention to business, but all his hours of leisure were spent and all his recreation taken in the pursuit of his favourite subject geology.

In his reply to the remarks which Sir Henry De la Beche made on presenting the Wollaston medal to him in 1849, he said:

"It is true that I entered upon this field as a student and for relaxation, but the interest and difficulties of the subject speedily induced me to take it up with more earnestness and determination, and eventually led me to extend the inquiry over an area which I, at first, never contemplated.

"The Tertiary geology of the neighbourhood of London may be wanting in beauty of stratigraphical exhibition and in perfect preservation of organic types, but in many of the higher questions of pure geology—in clear evidence of remarkable physical changes, in curious and diversified palæontological data, however defaced the inscriptions, which is after all but a secondary point—few departments of geology offer, I think, greater attractions.

"The pleasure I have derived from the study of the remarkable phenomena which have come before me in the course of the investigation has far outbalanced the few obstacles I have had to contend against. I, in fact, feel deeply indebted to geology, as a source of healthful recreation, as an inestimable relief and abstraction in due season from the cares frequently attendant upon the active duties of life, for its kindly and valued associations, and above all for the high communing into which it constantly brings us in the contemplation of some of the most beautiful and wonderful works of the creation" (p. 66).

Yet most of his work, undertaken and carried on in the true scientific spirit, bore directly, as it turned out, on questions of the greatest economic importance. This was, however, by accident, for he studied the Coal Measures in early life only because his holidays were spent at Broseley, where he got interested in the geology of Coalbrook Dale. And similarly the Tertiary and Cretaceous rocks of the London district offered in later life the most accessible sections, and so he plunged with his usual zeal into their discrimination and classification with no ulterior view to the practical application of the information he was then acquiring. But the knowledge which he gained of the characters and sequence of both these groups of formations was afterwards of immense value to the country, and we find him not only a member of the Coal Commission, but also one of the most trusted authorities on water-bearing strata.

His paper on Coalbrook Dale is a masterly sketch in which the fossils of different horizons are distinguished and the stratigraphical structure of the district is worked out with great accuracy and well illustrated by maps and sections.

To give an idea of his work on the Tertiary strata would be to give a sketch of Tertiary geology which is not wanted in a notice of this kind, for he established the classification which is now adopted with very slight modification.

He followed up the strata to the newest beds, and soon took part in the discussions which arose respecting the age and origin of the Glacial and post-Glacial deposits—controversies not yet settled, and inquiries out of which suggestions of new difficulties yet to be explained still continue to arise.

It is very interesting to follow the progress of opinion respecting the association of the remains of man with those of extinct animals in the river gravels, whose antiquity was further proved by their relation to the

physical geography of the country. There were doubts also as to the objects from the occurrence of which the presence of man was inferred, for, except in some very doubtful instances, it was not his bones that were found, but only flints roughly fashioned into serviceable instruments. A good sketch of the development of the inquiry appeared some years ago in *Blackwood's Magazine* (vol. clvii., June 1895, p. 939).

M. Boucher de Perthes had conceived the idea that so it must be, but it was long before he found sufficiently convincing evidence of the fact. At last, however, after Boucher de Perthes had been excavating, collecting, talking, and writing about it for years, Dr. Falconer visited him and acknowledged that a good *primâ facie* case had been made out, and wrote to Prestwich to say that he ought to look into it. Prestwich accordingly made a pilgrimage to Abbeville, and came to the conclusion that there were in Boucher de Perthes' collection flints which had undoubtedly been wrought by man, which had been found in undisturbed ground, and which were of the same age as the remains of the extinct mammalia found with them.

Boucher de Perthes supported a good theory with much bad evidence, and we must bear in mind from all that passed then that there is need for caution in disbelief as well as in belief, and it may be that Prestwich's conviction may prove well-founded, that in the plateau gravels of Kent and Wiltshire there are flints worked by man of much earlier date than the palæolithic implements the genuineness of which he had with so much skill and pertinacity established. At present, however, the evidence as to these Palæotaliths or Eoliths, as they have been called, is not quite satisfactory, for natural forms have been exhibited with too much confidence as the work of man.

The view that there has been a great submergence of our island since glacial times will probably turn out to be correct, though it may be that the lapse of time over which it extended has not been rightly estimated. But the opinion that the phenomena could be best explained by submergence of such a transitory and tumultuous nature as to be properly called a flood will not at present command general acceptance. Prestwich himself seems to have been willing to qualify very considerably the statements involving the idea of a flood.

In endeavouring to interpret the story of the later accumulations it was, of course, most desirable to search for any local conditions which tended to preserve the relics which were chiefly relied upon as evidence, and such conditions appear to be furnished by the caves in which are found sealed up the remains of man who lived or buried his dead there, of the wild beasts which crawled in to die, or dragged in the bones of other dead animals to feed upon at their leisure.

Prestwich therefore paid much attention to the hyæna dens and other caves discovered from time to time round the coast or in inland cliffs. His object was to establish some chronology from the associated objects, or make out certainly any relation between the contents of the caves and of the raised beaches or river terraces which were by degrees beginning to be understood.

Prestwich was so impressed by the vastness of the changes which had taken place even during the latest geological ages that he began to doubt whether the operations of nature which we see going on around us were sufficient to bring about such great results, and he further saw evidence of more violent action in many of the phenomena of recent date. While not reviving the old cataclysmic views, he questioned the wide application of the uniformitarian doctrines as taught by Lyell; but their views will be easily reconciled, first, by the doctrine that local catastrophic action is quite consistent with continuity of causation; and, secondly, by the admission of the inevitable effects of ever-recurring earth movements in hurrying up or retarding the operations of denudation and deposition.

The theory that there exists an underground plateau of Palæozoic rocks extending at an inconsiderable depth beneath the Secondary and Tertiary rocks of East Anglia, interfering as at Ware with the water supply, and raising hopes everywhere of a new source of coal supply, which was partly suggested by De la Beche and put into shape by Godwin Austen, and which was verified at Harwich, Ware, London and Dover, was, of course, a subject of the greatest interest to Prestwich, and the progress of the investigation was largely advanced by him.

He was a pleasant letter writer, but as time went on he seems to have confined himself more and more to the object for which he had taken up his pen, and that was generally some scientific point. His sense of humour was strong, but showed itself more in conversation than in his letters.

At his pleasant home on the chalk hills he spent many happy days in later life, and there he breathed his last soon after Royal favour had recognised his long services by designating him as one of the recipients of the honours granted on New Year's Day 1896.

His memoir is written in a loving spirit, and there will be few amongst its readers who do not entertain towards him that affectionate feeling of regard and respect that would be very ill content with any other treatment.

## *METEOROLOGY, OLD AND NEW.*

*Neudrucke von Schriften und Karten über Meteorologie und Erdmagnetismus.* Herausgegeben von Prof. Dr. G. Hellmann. Wetterprognosen und Wetterberichte des xv. und xvi. Jahrhunderts. (Berlin: Asher and Co., 1899.)

*Annals of the Astronomical Observatory of Harvard College.* Vol. xxxix. Pp. iv + 153. Part I. Peruvian Meteorology, 1888–1890. Compiled and prepared for publication by Solon I. Bailey, Assistant Professor of Astronomy, under the direction of Prof. E. C. Pickering. (Cambridge, U.S., 1899.)

*Annales de l'Observatoire national d'Athènes publiées.* Par Démétrius Éginitis, Directeur de l'Observatoire. Tome I. Pp. xxi + 395. (Athènes: Imprimerie Nationale, 1898.)

DR. HELLMANN has devoted himself with indefatigable application to the unearthing of those rare publications which illustrate the growth of an intelligent interest in the sciences of meteorology and magnetism, when these subjects first attracted attention

after the period of the Renaissance. Our columns have from time to time borne witness to his energy and to the merit of his selections. The present volume constitutes the twelfth of the series, and in matter of interest is not one whit behind any of its predecessors; while the beauty and fidelity of the facsimile reproductions will be acknowledged on all hands. In a short preface, Prof. Hellmann sketches the growth of the popularity of treatises on weather prediction, which circulated in great numbers before the close of the fifteenth century, whether in the form of almanacs or works of even greater pretension. The substitution of the language of the country for the learned Latin, which was in more general use prior to 1470, gave a great stimulus to the circulation, and on the continent of Europe these pamphlets and broadsheets won for themselves a warm welcome. Of the remains of this large harvest which have come down to us, Prof. Hellmann offers some typical selections, accurately reproduced as they circulated from hand to hand among various nationalities. Italy seems to have been earliest in the field to minister to the popular longing for this kind of literature, but later had to give way to German perseverance, which has won for itself the doubtful reputation of producing the greatest number of these almanacs. Prof. Hellmann has already given a catalogue of 600 distinct publications, but later study has made him acquainted with many more, and he now places the number at not less than 750. England and France, judged by the number of examples that have been preserved, do not seem to have exhibited anything like the same eagerness for the possession of this kind of writing which Germany, Italy, and the Netherlands exhibited. But specimens of all these various productions, graduated in point of time throughout the sixteenth century, are now made accessible to the student. England is represented by "An Almanacke and Prognostication" for 1555, by A. Aksham, priest and physician, which in the main outline differs but little from much earlier productions. An excellent example, dated 1506, due to the fancy of Leonardo de Richi, is presented in facsimile. As a rule it may be said that these various prophecies and indications begin with a dedication to some notability, then follow predictions relating to fruitfulness, conditions of health, wars and peace, in which is prefigured the fate of nobles and States, and towns and countries, and finally the times of moon changes are added, a knowledge of which is not only necessary for predicting the weather, but indicate the proper times for blood-letting and surgical operations. A modest section suffices for indicating the variations of the weather. We may quote an example from the Prognosticon of Julian de Blanchi which relates to October: "October ventosus et in eo aquae et tonitrua apparebunt, et dies dispositi ad aliquam aeris alterationem erunt iii., v., vii., xiii., xx., xxii., xxvi., xxxi."

The second volume quoted above refers mainly to an inquiry into the climate of Peru, but possesses a feature of distinct interest, to which we shall refer later. Peru has been roughly but conveniently divided into three regions, marked by the peculiarities of coast, mountain and forest climate. More particularly in two of these different localities, the enterprise of Prof. Pickering has established fully equipped meteorological observatories, and the present volume contains the discussion of the measures made at these stations between 1888–90. Mollendo, nearest the coast, is situated on the narrow strip of rock and sand which marks the abrupt rise of the continent from the waters of the Pacific. Chosica, further inland, is about twenty-five miles north-east of Lima. Here the climatic conditions fall midway between those of coast and mountain; for the land rises gradually from the ocean in successive ranges, each higher than that preceding it. The station itself stands on the summit of a conical mountain some 7000 feet high. Vincocaya and Puno, the two remaining stations in actual working order, are distinctly of the mountains. The former is near the crest of the Western Cordillera, on a desolate plateau nearly 15,000 feet in elevation. Puno is on the western shore of Lake Titicaca, and is typical of the great plateau which lies between the Western Cordillera and the Bolivian Andes. A few observations were also made at Pampa Central, near the central western part of the great desert of Atacama. Prof. Pickering describes this region as possibly the most barren on the earth. Not even a cactus breaks the monotony of the view near this town. The ground is rich in nitrates and other salts of immense commercial value; but the absence of rain on a soil of this character makes the region absolutely barren. In districts so uninviting and remote from the conveniences of civilisation, observers are found who, often without any hope of pecuniary reward, devote themselves to the maintenance of a continuous meteorological record. Self-registering apparatus is sometimes used, but the monotonous registration of the amount and character of cloud and similar data which go to decide the climate of a country, can only be secured by regular personal supervision; and though Prof. Pickering is obliged to reject some of the observations, owing to a suspicion of error, we think he is to be congratulated on securing an amount of co-operation which could hardly be anticipated in so inhospitable a country.

But the feature of special interest, and one that gives to the volume something of the charm that attaches to a work on travel, is the description of the establishment of two meteorological observatories near the summit of the lofty El Misti, a mountain which dominates the city of Arequipa, and from its symmetry, height and proximity constitutes the most imposing feature in the range of mountains that nearly encircles that town. It goes without saying that the approach to the summit is attended with great difficulties; but, rising as it does to a height of some 20,000 feet, or about 12,000 feet above the elevated plateau on which Arequipa stands, this truncated cone offers advantages to the meteorologist intent on studying the behaviour of the atmosphere at considerable elevations not less than the clear skies of Arequipa present to the practical astronomer. But only the most energetic would suggest to themselves the possibility of pursuing meteorological observations in a spot so inaccessible. Prof. Bailey gives us some account of earlier attempts, made at rare intervals, to reach the top of this venerated peak, some undertaken for the benefit of science, some from curiosity, but all, whether successful or not, accompanied with considerable danger and fatigue. Yet an observatory to be useful must be regularly and systematically visited. A tolerably

permanent mule track seemed to Prof. Bailey the best and only means of reducing the hardship of the ascent, and with true American ingenuity and enterprise he undertook the task of making a passable road up the sides of this barren mountain, over the remains of ancient lava streams and past huge slopes of volcanic sand, whose angle of ascent was oftentimes as much as 30°. Indians and Spaniards alike ridiculed the attempt, but Prof. Bailey persevered with his design, in spite of fatigue, mountain sickness, sulphurous vapours and the yielding character of the ground, into which the feet of the mules would sink six inches at each step. How he finally succeeded is modestly described in a chapter of great interest, to which we must refer for particulars. We can only record that at an altitude of 15,000 feet, approximately that of Mont Blanc, but in this latitude beneath the line of perpetual snow, the first observatory hut was set up, and, cheered by this success, it was resolved to attack the summit of the crater, and now eight feet above the highest point of the mountain a Robinson anemometer is successfully mounted, giving a continuous record of wind velocities in this elevated region. Other instruments from which records are obtained are a Richard self-registering hygrometer and thermograph, which register continually for ten days without interruption. Special thermometers and apparatus are mounted in a hut six feet square and seven feet high, on the very top of the mountain, a monument of well-directed vigour and indomitable resolution on the part of the director. We can but offer our congratulation on the completion of a work of so much difficulty, and hope that the results will equal in interest the labour by which they have been secured. Whatever may be the final outcome of mountain meteorology, Prof. Pickering has definiteiy secured, through the untiring efforts of Prof. Bailey, a chain of meteorological stations from Mollendo on the Pacific to the headwaters of the Amazon.

We have, unfortunately, but little space to do justice to the work of M. Éginitis. A thick volume filled mainly with meteorological observations and their discussion is apt to prove somewhat wearisome reading, but the director has managed to introduce some features of interest. In fact, the publication of the volume itself, indicating as it does the renewed activity of an observatory which has been practically non-existent since the death of Dr. J. F. Julius Schmidt, cannot but be welcome, and we may venture to hope that the observatory from which so much valuable work has emanated in the past will again be found among the institutions that contribute to the progress of science. M. Éginitis gives in an interesting chapter the history of the observatory since its erection, a record which in spite of sundry interruptions should prove inspiriting, since it demonstrates that the energy and ability of successive directors have risen superior to the difficulties inseparable from small instruments and straitened means. The volume is divided into two parts; in the first the climate of Athens is discussed, the treatise being enlivened by the introduction of many extracts from the old classical authors. In the second part are given the readings of the various instruments, by the discussion of which the climate is determined.

W. E. P.

## *MACHINES FOR THE LIQUEFACTION OF GASES.*

*Liquid Air and the Liquefaction of Gases.* By T. O'Conor Sloane, Ph.D. Pp. 365. (London: Sampson Low, Marston, and Co., Ltd., 1899.)

THIS book may be regarded from three points of view: (1) as a popular account of recent work and experiments; (2) as a scientific examination of the same: and (3) as a historical summary and appreciation of invention in a special branch of science. As an instalment of popular science it has much interest. Readers who, guiltless of any exact science themselves, like to know what is going on in the modern scientific world, will find here a good deal that will help them to understand the significance of such steps in advance as are from time to time reported. As an exact critique of the progress of invention it is not a success. On p. 300, for instance, Dr. Sloane says: "The origin of the methods used by Tripler, Hampson and Linde can be studied in the records of the Patent Offices." Then referring to Mr. Tripler's patent of 1893, he says the apparatus therein described "is based on self-intensification for the production of cold. The Joule-Thomson effect is not appealed to in it." Shortly afterwards he says: "Linde and Hampson have both invoked" the Joule-Thomson effect "as the principle on which their machines operate." The teaching here, that, whereas the initial cooling in the Linde and Hampson machines is identical with the Joule-Thomson effect, it is in the Tripler machine produced in some other way, is entirely without justification and contrary both to good science and to common sense. The machines are all three based on the Joule-Thomson effect, and all three involve the use of self-intensification, while neither of these means is applied in Mr. Tripler's 1893 patent. More astonishing still, if Dr. Sloane is to be regarded as a scientific writer, are his approving references to this patent (its number, which he does not give, is 4210). This patent Dr. Sloane accepts as giving "a clear description with drawings" of a self-intensive refrigerator from which Mr. Tripler's present apparatus is derived. The apparatus is not a refrigerator at all, for it contains a fatal fallacy, the omission of cooling coils after the pump, to remove the heat of compression; while the circuit is so arranged that for liquefying air no such coils could be introduced. The apparatus therefore, designed to produce cold, is a generator of heat. Secondly, even if it produced initial cooling, as expected, such cooling could never be intensified, since there is no self-intensive interchanger. An interchanger, to make the cooling effectively self-intensive, must have one end at the higher temperature, where the compressed air enters, the other end, where this air expands, at the extremely low temperature, and a continuous gradation of temperatures between them. In Mr. Tripler's patent there is no interchanger in which such an arrangement is possible. Again, on p. 295, Dr. Sloane praises Mr. Tripler's apparatus for its extreme simplicity, as using no refrigerant; and after describing Dr. Linde's more complex laboratory system, with its preliminary refrigeration by ice and salt, he says, on p. 320, that the Hampson

and Linde systems are very similar, and work "precisely on the same lines." The truth is that the Linde apparatus works with air at three pressures, uses preliminary refrigeration by ice and salt, has widely coiled helices consisting of three pipes placed concentrically one within the bore of another, and takes from two to three hours to liquefy air; while the Hampson and Tripler plants, working from a compressor, both have air at two pressures only; both use no preliminary refrigeration, both have simple pipe closely coiled, and both liquefy air in less than fifteen minutes. It would therefore have been more correct, since the Hampson machine is the older of these two, to change the names used by Dr. Sloane, and say that the Tripler apparatus "is very simple, and resembles very much the" Hampson "apparatus, and it works precisely on the same lines."

The salient feature of the book, as a historical summary and appreciation, is the glorification of Mr. Tripler and American invention. The greatness of Mr. Tripler's achievements is compared to his advantage with the paltry efforts of European experimenters in many places, as on pp. 255, 289, 290, 355, and 356; and on p. 296 he is roundly called 'the originator of the self-intensive system." Dr. Sloane's repeated use of the phrase "back of" instead of "behind" suggests that he is probably an American; and if that is so, patriotism might be allowed to excuse the over-laudation of a fellow-countryman in cases of real merit. It cannot, however, justify the ascription of unreal achievements. Mr. Tripler did not show to the public his liquid air made by the self-intensive method till 1897, nearly two years after that method had been published and fully described in Europe; and as he has produced no evidence of having used it privately before, he cannot be accepted as its "originator." Dr. Sloane, it is true, in a summary of Mr. Tripler's work as the inventor of the self-intensive process, says on p. 288 that "about 1891 air was liquefied" by that gentleman. If this be true, both Dr. Hampson and Dr. Linde must give up their claims to priority; but something more than this vague and unsupported statement is necessary to prove that Mr. Tripler had invented the process before November 1894 and May 1895, the earliest authenticated European dates for the invention. It is indeed inconceivable that, if Mr. Tripler had understood the subject well enough to invent and successfully work the process in 1891, he could in 1893 have devised the futile and absurd scheme described in his patent of that year referred to above. Mr. Tripler's later apparatus, too, is insufficiently explained and authenticated if his claims to the invention of it are to be seriously considered. Dr. Sloane must know that the chief interest of this process centres in the arrangements for expansion and interchange of temperatures, and in illustrating the European systems he very properly gives sectional views which clearly explain the nature of these arrangements. But in illustrating Mr. Tripler's machine, while he gives needless views and descriptions of the rooms, the people, and such well-known appliances as three-stage compressors, coolers, and washers, he shows only the outside of the vitally important interchanger. Why did not Dr. Sloane ask for sectional views of this and of the mysterious "special valve, the invention of Mr. Tripler"? We could then have judged how far they really differ from those shown and used in Europe nearly two years before. He informs us in the preface that his requests for assistance in the compilation of his book met with quick response from Mr. Tripler among others. In connection with liquid-air processes there has been too much mystery made, the public being freely asked for their admiration and faith without being frankly made acquainted with the details of an inventor's process and the evidence of his originality. Strangely enough Dr. Sloane, who so complacently accepts Mr. Tripler's mysteries, is himself, on p. 238, an objector to their prevalence in similar work at the Royal Institution. So much attention has lately been excited by Mr. Tripler's scheme for using liquid air as a means of providing unlimited power without cost, that Dr. Sloane might fairly have been expected to give his unscientific readers some useful guidance by explaining how these schemes violate hitherto inviolable laws as to the latent heat of volatilisation of gases, and are, in fact, blunders due to a mistaken interpretation by Mr. Tripler of one of his experiments. Instead of this, Dr. Sloane, on p. 289, gives Mr. Tripler's schemes a mild approval and support by saying that

"the utilisation of the low-grade heat energy of the universe presents nothing essentially impossible. This heat Tripler hopes to utilise. If it is utilised, &c. . . ."

Such toleration of Mr. Tripler's amazing proposals would disqualify any writer as a serious scientific critic.

## A MANUAL OF ANTHROPOLOGY.

*The History of Mankind.* By Prof. Friedrich Ratzel. Translated from the second German edition by A. J. Butler, M.A.; with Introduction by E. B. Tylor, D.C.L., F.R.S. With coloured plates, maps, and illustrations. Three volumes. Pp. xxiv + 486 + 562 + 599. (London: Macmillan and Co., Ltd., 1896.)

THE student of anthropology will welcome this handsome English edition of Prof. Ratzel's "Völkerkunde" as an invaluable work of reference for the numerous and scattered branches of his study. Perhaps no department of science embraces so large a field as the study of man and the history of civilisation, and in proportion to its complexity the greater is the necessity for some general guide to the subject. On the first publication of the work in the years 1885–88 it was at once recognised as the most comprehensive survey of the state of our knowledge of the lower races of mankind that had hitherto appeared, and since that time it has maintained its position in Germany as the standard popular work on the subject. The present English translation has been made from the second German edition and may therefore be regarded as in all essentials abreast of recent research. In his Introduction, Prof. Tylor has called attention to the large number and accuracy of the illustrations with which the book is furnished, and which he well remarks surpass in excellence any that have yet been issued in similar works intended for general circulation. The importance of good illustrations in contrasting the successive stages of the development of the human race cannot be over-estimated, for they convey far more to the general

reader than long descriptions and strings of technical terms.

In the main the book may be regarded as the best introduction yet available for the beginner who wishes to gain a general knowledge of anthropology and its results as applied to the study of the barbarous and more primitive races of the world. The book is not intended as a guide to the literature of the subject, nor as a work of reference for every specialist in his own department of the science, but is throughout addressed to the general reader. With this aim in view, Prof. Ratzel has disencumbered his pages of all foot notes and references to authorities, and has applied himself to giving, as far as possible, a sketch of results without overloading any portion of his work with the discussion of technical or unnecessary detail. In so doing, the author has been well advised, for not otherwise could his outline have approached completeness within the limits to which it was necessarily restricted.

Prof. Ratzel has treated his subject in five sections or books, the first of which is introductory, while the others roughly correspond to the principal ethnological divisions of the human race. In Book i. he has given a very clear sketch of the principles of ethnography, describing the distribution and general aspects of mankind, the rise of civilisation, and the development of language, religion, science and art, and family and social customs. The next three books describe the more important undeveloped races of the present day. Thus Book ii. deals with the American Pacific group of races, under which heading are included the races of Oceania, the Australians, the Malays and Malagasies, the American tribes, including the ancient civilised races of America, and the Arctic races of the Old World. Book iii. is devoted to the light stocks of South and Central Africa, such as the Bushmen, the Hottentots and dwarf races, while Book iv. deals with the Negro races found throughout Africa. Book v., the last section of the volume, gives a general sketch of the cultured races of the Old World. This brief summary of the contents of the volumes will serve to indicate the very comprehensive character of this history of mankind. The treatment of some of the sections of the book might perhaps have been a little fuller with advantage, but, even in sixteen hundred pages, considerable condensation was obviously necessary; and with so trustworthy a guide as Prof. Ratzel the reader need not fear that any essential facts have been inadvertently overlooked. A special word of praise should be given to Mr. Butler, not only for the excellence of his translation, but also for the care with which he has verified and corrected the descriptions of the numerous illustrations in the text.

## *OUR BOOK SHELF.*

*A Theory of Reality.* By Prof. George Trumbull Ladd. Pp. xv + 556. (London: Longmans, Green, and Co., 1899.)

PROF. TRUMBULL LADD'S "Theory of Reality," though intelligible in isolation, is a sequel to his "Philosophy of Knowledge" published in 1897, and a link in a chain of development beginning so far back as 1887. The Yale professor makes severe demands upon his public. His voluminous and discursive activity has now produced its fifth harvest, and we take it that there is at least a sixth to come. A certain condensation, therefore, and the taking of some things, *e.g.* the propriety of metaphysics, for granted, would not be out of place. Whatever be the case with the category of time, the reader's time is not unlimited. As compared, however, with its immediate forerunner, the irrelevance and repetition in the present work are only relative. And the review of his intellectual progress, with which the book closes, accounts in a not uninteresting way for his tiresome method of exposition.

Prof. Ladd's theory, which is avowedly speculative, may be described as a Realism of Spirit. It takes its starting-point from self-felt activity, finds "trans-subjective" elements involved in every cognition, and projects upon these by way of analogy the notion that they, too, are real centres of self-activity. "Things are known as imperfect and inferior selves." "The inner reality of all beings is spirit." "The transcendental reality of time is the all-comprehending life of an absolute self." "Viewed in its ontological aspect, all the growth of man's cognitive experience reveals the being of the world as a unity of force, that is constantly distributing itself amongst the different beings of the world so as to bestow on them a temporary *quasi*-independence, while always keeping them in dependent inter-relations, for the realisation of its own immanent ideas." This is not idealism, though in its affirmation of spiritual unity it steals the idealist's thunder. The nature of our knowledge of self and of the dynamical character of its agency necessitates realism; though, on the other hand, because connection according to some law must be predicable of reality, we are able, in the most satisfactory chapter of the book, to consider reality as an actual harmony of categories.

The interdependence, and neither independence nor dependence, of the categories is admirably treated, and Prof. Ladd discusses each in turn. He has in general (Pref., p. ix.) submitted the chapters which come into closest relations with the physical sciences to expert friends and colleagues. The treatment, however, of matter and ether as separate kinds of entity, though it may follow from his scientific definition of matter, presents difficulty to the metaphysical reader. Is ether then immaterial? The explanations of pp. 447–448 only partially solve the knot. Nor is it possible to agree with the symbolisation of time as a continuous flow of $n$ infinites, and of space as in each moment an infinite content which equals and is known to equal $n$ terms (p. 250). Prof. Ladd's point is, of course, to express the infinite simultaneous, but his symbols are misapplied.

H. W. B.

*Great and Small Game of Africa; an Account of the Distribution, Habits, and Natural History of the Sporting Mammals, with Personal Hunting Experiences.* Edited by H. A. Bryden. Pp. xx + 612; illustrated. (London: Rowland Ward, Ltd., 1899.)

THIS magnificent volume is a unique work on the subject of which it treats; the greater part of the text being written by well-known African sportsmen (among whom Mr. F. C. Selous occupies a prominent position), while a naturalist is responsible for the classification, nomenclature, and the leading distinctive features of the main groups. It is thus written throughout as the result of actual experience, and accordingly possesses a value far above the ordinary type of natural histories. Although mainly written for sportsmen, the professional zoologist cannot fail to find much matter bearing upon his own studies; and the African sportsman should no longer have any difficulty in identifying any of the species (unless they be new) which may fall to his rifle. The coloured illustrations, which for the most part are restricted to figures of the heads of the various species, are all that can be desired, both from an artistic and a zoo-

logical point of view. The book is invaluable to all interested in the natural history of Africa, and is especially important as indicating the number of game animals to be met with in British territories and dependencies.

R. L.

*An Introduction to the Carbon Compounds.* By R. H. Adie, M.A., B.Sc. Pp. viii + 90. (London: W. B. Clive.)

WITHIN the brief compass of this work the author aims at introducing the student to some of the chief groups of the carbon compounds, as represented by familiar substances, and at the same time at providing a series of experiments to illustrate the properties and reactions of these compounds. Thus the subject of the hydrocarbons is developed from an examination of the properties of coal gas, which leads to the study of marsh gas, ethane, olefine, acetylene and benzene. A feature of the book is that aromatic compounds are described along with fatty derivatives belonging to the same group, phenol along with alcohol, benzoic and salicylic acids along with acetic acid, aniline along with ethylamine, &c. This arrangement of the matter produces, no doubt owing to the severe compression, a somewhat disconnected effect, as it in many cases prevents a complete and logical discussion of the constitution of the compounds which are mentioned. This renders the book less suitable for absolute beginners than for students who have already a slight elementary acquaintance with the subject, and to these it cannot fail to afford valuable assistance. The experiments are on the whole well selected, but they are conducted on purely qualitative lines, no attention being paid to that important factor—the yield.

## LETTER TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

### On the Deduction of Increase-Rates from Physical and other Tables.

PROF. PERRY has called my attention to a want which sometimes arises in making practical deductions from tables. Take the following example.

| $\theta$ C. | $p$ | $\Delta p$ | $\Delta^2 p$ | $\Delta^3 p$ |
|---|---|---|---|---|
| 90 | 1463 | | | |
| | | 302 | | |
| 95 | 1765 | | 49 | |
| | | 351 | | **8** |
| 100 | 2116 | | **57** | |
| | | **408** | | 5 |
| 105 | 2524 | | 62 | |
| | | **470** | | 8 |
| 110 | 2994 | | **70** | |
| | | 540 | | **8** |
| 115 | 3534 | | 78 | |
| | | 618 | | |
| 120 | 4152 | | | |

The table gives in the second column the pressure of steam for the temperatures stated in the first column, which proceed by equal steps of 5°. The question is, how best to derive from these data the value of $\frac{dp}{d\theta}$ at one of the stated temperatures, say 105°.

The column $\Delta p$ gives the differences between consecutive values of $p$. The column $\Delta^2 p$ gives the differences between consecutive values of $\Delta p$, and so on. The third differences $\Delta^3 p$ exhibit so much irregularity that it is not worth while to proceed to fourth differences.

It is obvious that the required result is greater than $\frac{1}{5}$ of 408, and less than $\frac{1}{5}$ of 470. Half the sum of these two is a fair first approximation. Closer approximations can be obtained by means of the numbers printed in large type. Let the downward sloping series 470, 70, 8 be called $d_1$ $d_2$ $d_3$, and the upward sloping series 408, 57, 8 be called $u_1$ $u_2$ $u_3$. Also let the common difference 5° be denoted by $h$.

It is known to mathematicians that $h\frac{dp}{d\theta}$ is theoretically equal to $d_1 - \frac{1}{2}d_2 + \frac{1}{3}d_3 - \&c$, and also to $u_1 + \frac{1}{2}u_2 + \frac{1}{3}u_3 + \&c.$, both series being supposed to be continued till we reach an order of differences that vanishes.

In physical tables, usually no column of differences vanishes exactly, and the two series will not exactly agree. The question is, how to get the best practical approximation out of them. The most obvious plan is to add them, and write

$$2h\frac{dp}{d\theta} = (d_1 + u_1) - \tfrac{1}{2}(d_2 - u_2) + \tfrac{1}{3}(d_3 + u_3) - \&c.,$$

then to take the first bracketed expression, the first two, the first three, &c., as first, second, third, &c., approximations. But it will be found on trial, in the present instance and in most instances, that the second approximation so obtained is less exact than the first.

I find, on looking into the matter strictly, that the proper second approximation is

$$2h\frac{dp}{d\theta} = (d_1 + u_1) - \tfrac{1}{6}(d_2 - u_2).$$

This equation would be exact if $p$ were capable of being expressed in the form

$$p = A\theta + B\theta^2 + C\theta^3 + D\theta^4.$$

As applied to the example before us, it gives 87·7 as the value of $2h\frac{dp}{d\theta}$, and 8·77 as the value of $\frac{dp}{d\theta}$. This is as close an approximation as is warranted by the data. The first approximation $(d_1 + u_1)$ is 87·6.

The two series $d_1 - \frac{1}{2}d_2 + \&c$, and $u_1 + \frac{1}{2}u_2 + \&c.$, carried each to three terms, give respectively 87·53 and 87·83.

The proper third approximation, which would be exact for

$$p = A\theta + B\theta^2 + C\theta^3 + D\theta^4 + E\theta^5 + F\theta^6,$$

is

$$2h\frac{dp}{d\theta} = (d_1 + u_1) - \tfrac{1}{6}(d_2 - u_2) + \tfrac{1}{30}(d_3 + e_3).$$

Another requisite is to determine $\frac{d^2p}{d\theta^2}$. When the fourth order of differences vanishes, I find that $d_1 - u_1$ is the accurate value of $h^2\frac{d^2p}{d\theta^2}$. In the present instance this gives

$$\frac{d^2p}{d\theta^2} = \frac{62}{25} = 2{\cdot}48.$$

The formulæ most employed hitherto for this purpose are

$$h^2\frac{d^2p}{d\theta^2} = d_2 - d_3 + \frac{11}{12}d_4 - \&c.$$

$$= u_2 + u_3 + \frac{11}{12}u_4 + \&c.$$

which, if we include two terms of each, give respectively $\frac{62}{25}$ and $\frac{65}{25}$.

When fourth and fifth differences are worthy of attention, the correction to be made for them consists in adding

$$\tfrac{1}{6}(d_1 - u_1) - \tfrac{1}{12}(d_2 + u_2)$$

to the first approximation $d_1 - u_1$.

To take account of fifth and sixth differences, this correction must be supplemented by a further addition of

$$\tfrac{1}{15}(d_1 - u_1) - \tfrac{1}{30}(d_2 + u_2) + \tfrac{1}{90}(d_3 - u_3).$$

Without occupying space by a detailed investigation, I may say that my plan of procedure is first to write down (by Taylor's theorem) the expansions for the first differences in ascending powers of $h$; then so to combine them in pairs by subtraction as to eliminate all even powers; then to eliminate $h^3$ from two of the resulting equations. This gives.

$$2h\frac{dp}{d\theta} = (d_1 + u_1) - \tfrac{1}{6}(d_2 - u_2)$$

when $h^5$ is neglected.

The next approximation is obtained by eliminating both $h^3$ and $h^5$ from three of the equations.

In the first operation for deducing $\frac{d^2p}{d\theta^2}$ the pairs are combined by addition instead of subtraction, thus eliminating all odd powers of $h$.

This gives $d_1 - u_1 = h^2\frac{d^2p}{d\theta^2}$ when $h^4$ is negligible. The succeeding approximations are obtained by eliminating first $h^4$ and then both $h^4$ and $h^6$.

J. D. EVERETT.

## THE PENYCUIK EXPERIMENTS.[1]

THE well-devised breeding experiments now in progress at Penycuik under the direction of Prof. J. Cossar Ewart, are, it need scarcely be said, of the highest interest both theoretical and practical. To the general biologist the subject of hybridisation affords a wide field for the investigation of laws of heredity, and especially of such subsidiary factors, whether real or only imaginary, as reversion, prepotency, saturation and telegony; while the question of the sterility of hybrids has important bearings on the general theory of evolution. But besides the purely scientific aspects of the problems which are now being attacked by Prof. Ewart, there is also their practical application, which appeals with much force to the interests of the breeder of stock. It is of course true that the whole history of animals and plants under domestication may be said to provide a body of experiments in these and similar subjects on a very large scale; and it is undoubtedly the case that many of the questions referred to have been already answered, at least provisionally. The experience of many generations of breeders has led to the emergence of certain practical rules, which are seldom if ever disregarded by those whose interests are concerned in the rearing of animals with a definite object. But it still remains doubtful how far the widely-accepted doctrines of fanciers and other breeders rest upon any firm scientific basis; and it is certainly most desirable that precise experiments should be undertaken with the sole object of arriving at the truth in such matters as prepotency, telegony and the effects of inbreeding. It cannot but be to the advantage of breeders if empiric methods founded on vague conjecture and imperfect generalisation can be made to give place to a rational system derived from exact knowledge of facts. Prof. Ewart's design ought therefore to meet with a warm welcome in scientific and practical quarters alike.

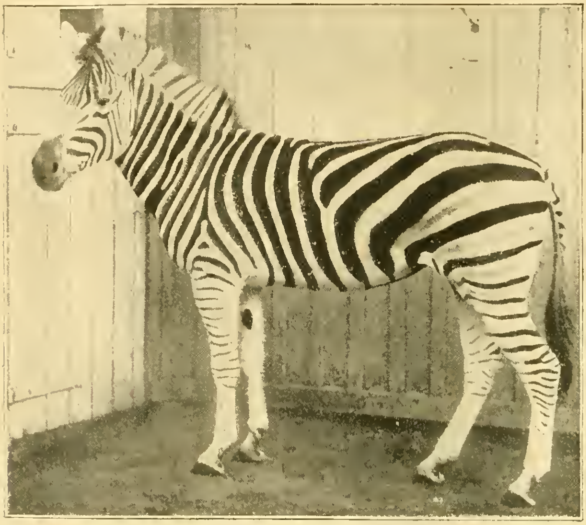

FIG. 1.—Matopo.

The volume before us contains an account of such results of the author's experiments as are now sufficiently mature for publication. It is not so much a book as a re-issue in book form of three papers that have already seen the light, together with a general introduction which, to some extent, summarises and supplements the information subsequently given. Prof. Ewart remarks that "as the problems under consideration are not of a kind that can be settled off-hand, and as one inquiry has begotten others, some years must elapse before a complete and systematic account is possible." Meantime, he thinks, the publication of his results in their present form "will indicate the lines along which the inquiries are proceeding, and also the kind of answers likely eventually to be made to some of the questions." Regarded in this way as an instalment, the volume well fulfils its purpose.

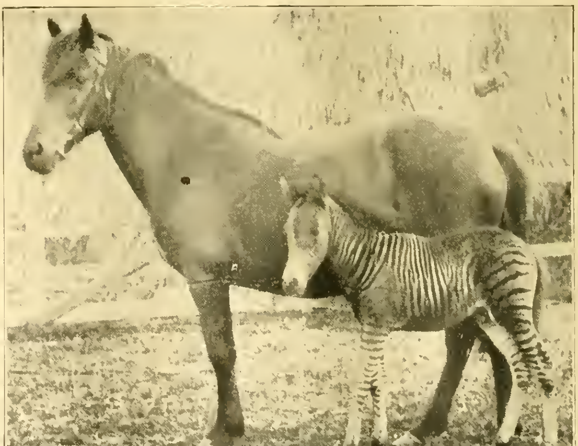

FIG. 2.—Romulus (seven days old) and his dam, Mulatto.

The first paper is chiefly devoted to a detailed descrip-

[1] "The Penycuik Experiments." By J. C. Ewart M.D., F.R.S., Regius Professor of Natural History, University of Edinburgh. Pp. xciii + 177. (London: Adam and Charles Black, 1899.)

tion of "Romulus," a hybrid colt whose sire "Matopo" is a Burchell's zebra of the *Chapmani* form, and whose dam "Mulatto" is an Island of Rum pony. "Mulatto" was afterwards crossed with a grey Arab stallion "Benazrek," and a description of her second foal, which unfortunately only lived for a little over five months, is given in the last paper under the head of "Telegony and Reversion." The foal in question was naturally a centre of great interest, inasmuch as from its parental history it afforded an opportunity for the operation of the alleged principle of telegony. The answer returned by nature to this particular interrogation was, as is so often the case, ambiguous. The colt was certainly striped, but the stripes were not like those of Mulatto's first mate; nor, on the other hand, did they entirely resemble those stripes often obscurely visible in ordinary foals. The evidence so far, though in no way conclusive, seemed to be capable of interpretation in accordance

FIG. 3.—Matopo.

with the theory of telegony. However, in the general introduction, after giving the results of a fresh comparison with pure-bred foals, and adding an account of three additional experiments of the same kind, the author concludes that in no one of these cases is it possible to maintain that infection, saturation, or telegony has taken place. The results of further trials with rabbits, dogs and pigeons have also at present been uniformly negative.

In the second paper, particulars are given of a further batch of hybrids sired by the same zebra stallion "Matopo"; the dams being respectively a Shetland and an Iceland pony, an Irish mare and a cross-bred Clydesdale mare. All presented points of interest, and the extent to which they resembled their sire or respective dams varied much, but it was found that even those which in several characters most distinctly suggested the zebra sire differed entirely from him in markings. According to Prof. Ewart, the markings of his hybrids accord fairly with those of the Somali zebra, which he regards as being the most ancestral in its colour-pattern of all recent Equidæ.

If this is really the case—and it is difficult to find any weak spot in the author's cautious yet cogent line of argument—the hybrids in question supply one more good illustration of Darwin's principle that the crossing of distinct species frequently leads to reversion. It may here be remarked that precisely the same conclusion seems to follow from the elaborate experiments in the hybridisation of insects recently conducted at Zürich by Dr. M. Standfuss. The latter investigator, it is true, speaks only of the "prepotency of the phylogenetically older" of the two parent species; but, while he refrains from actually using the term "reversion" with regard to his hybrids, he records the fact that some of them exhibit characters which must have belonged to an

FIG. 4.—Romulus.

ancestor of one of the parent species, though absent from the parents themselves.

With regard to the zebra hybrids now under discussion, the most striking point of difference in marking between "Romulus" and the other cross-bred foals on the one hand, and their common sire "Matopo" on the other, is the multiplication of stripes in the former, and the tendency to the production of a gridiron pattern over the rump. The last-named of these characters resembles the condition seen in the mountain zebra, an earlier form, according to Prof. Ewart, than the Burchell group, while the former point recalls the still more ancestral pattern of the Somali zebra. In the Shetland pony's hybrid, "Norette," the pattern over the hindquarters from the first resembled that of the Somali zebra; in the other hybrids, the markings of the same region, indeterminate at first, finally settled down into a form suggestive rather of the less remote stage marked

by the mountain zebra. The difference in the general system of striping between "Matopo" and his offspring is well brought out in the figures here reproduced, by the courtesy of the publishers, from Prof. Ewart's work. A more special point, but one of great interest, is that exemplified in the accompanying figures of the brow-stripes in "Matopo," in "Romulus," and in a Somali zebra. The numerous rounded arches shown on the forehead of "Romulus" are very different from the four or five acutely pointed arches of "Matopo," and clearly bear a much greater resemblance to the corresponding pattern of the Somali zebra. It should, however, be mentioned that a system of brow-striping not unlike that of "Romulus" occurs in Crawshay's zebra, a member of the Burchell group.

On one point of special importance the experiments have so far given results that, however interesting

FIG. 5.—Somali Zebra.

scientifically, are from the practical side disappointing. Following a suggestion of Captain Lugard, that zebra mules might possibly turn out to be immune to the disease communicated by the tsetse fly, and might thus help in solving some of the difficulties of African transport, Prof. Ewart, with great liberality, inoculated three of his hybrids with some of the tsetse organism at that time under investigation by Messrs. Blandford and Durham. The result of this experiment is not given in the present volume, but in the recently published *Proceedings* of the International Congress of Zoology at Cambridge it is stated that the inoculated animals, though apparently somewhat more resistant than horses, all died in about eight weeks.

The above-mentioned are a few only of the points of interest brought out by the remarkable series of experiments dealt with in the present volume, but enough has probably been said to show the importance of the problems which Prof. Ewart has set himself to solve, and the prospects of advance in knowledge which these researches hold out. It only remains to say a word in commendation of the general get-up of the book, and of the character and accuracy of the illustrations, which in many cases are reproduced from actual photographs. The absence of an index or detailed table of contents is a drawback, but this, like the frequent repetition of the same facts, is perhaps inseparable from the method of publication adopted. A tabular list of the hybrids, giving their parentage and the more important features of their aspect, might be a useful addition, as the reader finds it a little difficult at present to piece together the various details, scattered through many parts of the work, under their proper headings. But any small defects of this kind will, no doubt, be completely remedied in the connected and systematic account of the fruit of his researches which Prof. Ewart leads us to hope for at some future time. Meanwhile, the course of his experiments will be watched with keen interest by all those who realise the importance, both scientific and practical, of a right conception of the laws of heredity. F. A. D.

## PIONEER CLIMBERS.[1]

NOTWITHSTANDING what has been done by Coolidge and Freshfield, by C. E. Mathews and F. Pollock, for the pioneers in mountain climbing, there is still room for a book so comprehensive as that before us. Mr. Gribble has collected a quantity of interesting information, and prints at the end of his work several rare and curious documents. It is, moreover, not wholly restricted to the Alps, for it touches on early ascents in the Pyrenees and the Apennines. These, however, are distinctly subordinate; the interest, as is only natural, centres on the mountain backbone of Europe. This is many-sided, but on the present occasion we must restrict ourselves to aspects more or less scientific. A wide question is suggested at the outset: What caused that horror of mountains which was evidently so genuine among the chief nations of Europe till a period comparatively late in history? It was not felt by the Hebrew, as Mr. Gribble shows, but the Greek seems to have cared little for them, and the Roman detested them. Perhaps the practical nature of this people viewed them as an impediment to "imperial expansion," a sentiment hinted at in Napoleon's question, "When will the Simplon be practicable for cannon?" Moreover, in Rome's more luxurious days the rough roads, hard fare, and bad lodging of a journey across the Alps would naturally be objectionable. Classical influences, with a certain sympathetic similarity, may have caused the dislike once so general among our own countrymen, which has only been changed during the last thirty or forty years. These have witnessed a revulsion of sentiment which, whatever be its cause, is certainly one of the remarkable features in the later part of the nineteenth century.

But to pass from a general question to more particular topics, we can incidentally gather from this volume no bad idea of how some parts of scientific knowledge have advanced during the last four centuries. Prior to this epoch men knew little of science, and less of the mountains; pioneers were few, and the history of climbing—except when there was no help for it—was almost

[1] "The Early Mountaineers." By Francis Gribble. Illustrated. (London: T. Fisher Unwin, 1899.)

a blank. A monk of Canterbury, who crossed the Great St. Bernard late in the twelfth century, piously prayed that none of his brethren might come into that place of torment, and till long after that, though Leonardo da Vinci set a better example, and pilgrimages even began

FIG. 1.—John Tinner's Dragon.

to be made to the top of the Roche Melon, the Alps found few to praise them. Fancy invested them with superstitious terrors, of which the legend of Pilatus is an apt example, but here and there we come on the track of a sceptical traveller. In the first rank of these forerunners of the modern man of science is Conrad Gesner, who laughed at those stories, and was a true lover of the mountains. His successor, Josias Simler, even describes, about the year 1574, the precautions to be taken in crossing snowfields and glaciers, but the seventeenth century had begun before any careful note was taken of the latter. Then the fact of their motion was observed, and was communicated some years later, in 1669, to our own Royal Society; but the first speculations as to its cause appear to have been published by J. J. Scheuchzer, a professor, like the two first-named, at Zürich. Though evidently ill-adapted for mountain walking, he stuck bravely to it for some years at the beginning of the eighteenth century, and at last published two bulky volumes with numerous illustrations. These, in many respects, are interesting as a picture of Switzerland long before the coming of the tourist. But his book testifies to other changes, for it is full of dragon stories, and gives us portraits (such as that now printed) of many a loathly worm which now finds no representative on land, whatever it may do in the sea. Scheuchzer, in fact, though a good mathematician and a keen observer of minerals, plants, and even glaciers, had no critical faculty. He represents a type of student not yet extinct—the man whose first care is for "the literature of the subject," and who attaches an equal value to everything which appears in print. But before long in De Luc and Bourrit, and lastly in the really great De Saussure, scientific mountain travel begins, and the new era may be said to dawn. Now science finds in the Alps a workshop as well as a playground, and special memoirs such as that on Mont Blanc, noticed in these columns on June 15 (p. 152), are becoming common. Yet it is only just over a century since the last volume of "Voyages dans les Alpes" appeared.

Many curious illustrations, as we have intimated, are reproduced by Mr. Gribble, some indicating the strides which have been made in the representation of scenery, especially Alpine, during the last two centuries. The one given below was published about the year 1760, yet it bears little resemblance to nature, while some earlier than it are still more completely conventional. Incidentally the quotations in this volume throw light on the fauna of the Alps, showing, for instance, that bouquetin were common in districts from which they have long vanished. Indeed, odds and ends of curious lore abound in these pages; so that we have to thank Mr. Gribble, not only for an amusing book, but also for a valuable addition to Alpine literature. T. G. BONNEY.

## *BOWER-BIRDS.*

SINCE the year 1840, when Gould communicated to the Zoological Society an account of their extraordinary "runs," as they are locally called, the Bower-Birds of Australia and Papua have always attracted a large share of interest on the part not only of ornithologists but of students of the habits of animals. For in the construction of the "bowers" or "runs," from which they take their name, these birds stand absolutely alone, although the "playgrounds" of the Argus pheasant are comparable to the smooth patches cleared in the jungle by one species of Bower-Bird. On such an interesting subject it is of the utmost importance to have as much definite information as possible at first hand, and we are therefore glad to welcome the paper on the Australian representatives of the group, from the pen of an original

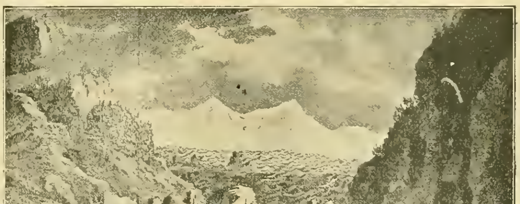

FIG. 2.—Grüner's view of the Lower Grundelwald Glacier.

observer—Mr. A. J. Campbell, of Melbourne—which appears in the last issue of the *Proceedings* of the Royal Physical Society of Edinburgh, special value attaching to this communication from the excellent photographs of "runs" and nests with which it is illustrated.

As there may be a lingering idea that the "runs" of these birds have some connection with nesting, it may be well to state that this is altogether a mistake. The nests, of which beautiful examples are figured by Mr. Campbell, present indeed no special features, being built at a height of from ten to fifteen feet above the ground, and usually containing at the proper season two, or sometimes three, eggs. These latter, however, cannot fail to attract the collector by their porcelain-like polish and beautifully pencilled markings. Thanks to the energy of Australian ornithologists, the nests and eggs of most of the species are now known, although some are rare and difficult to find.

"Run" of Great Bower-Bird. From a photograph taken in Western Australia by Mr. H. H. Johnston. (From the *Proceedings* of the Royal Physical Society of Edinburgh.)

Among the more elaborate types of "runs" or "bowers," the author figures those of the Satin Bower-Bird, the Spotted Bower-Bird, the Great Bower-Bird, the Queensland Bower-Bird, and the Regent Bird; the third of these being herewith reproduced. The photographs confirm previous statements as to the two types of decoration employed in these bowers, the taste of the Satin Bower-Bird displaying itself in the selection of bright-coloured parrot-feathers, while the other species named prefer bones and shells. The Spotted Bower-Bird may be described as a collector of sheep's bones (especially the vertebræ), whereas the Great Bower-Bird accumulates bleached shells. As is the case with the "Viscacherias" of the Argentine Pampas, in a Bower-Bird haunted country it is well to search the "runs" for any glittering objects, such as money or jewellery, which may have been lost in the neighbourhood. The amount of grass and sticks employed in some of these "bowers" is enormous, one structure being described as ranging from four to six feet in height.

In one respect Mr. Campbell does not agree with some writers, who have stated that the Cat-Birds (*Aeluroedus*) differ from other members of the group in that they build no bower, but content themselves with clearing a space of ground. No such spaces have, however, according to our author, yet been observed; and it is suggested that the birds may merely play on some fallen log. On the other hand, the Tooth-billed Cat-Bird (*Scoenopaeus*) of North Queensland does undoubtedly clear such spaces, upon which are laid at intervals a few leaves of one particular kind of tree. This represents the simplest type of "run," the most complex being that of the Gardener-Bird (*Amblyornis*) of New Guinea, which builds an orchid-covered hut, with a mossy lawn in front, ornamented with brilliant flowers and berries.

As to the object of these strange structures, Mr. Campbell has no new suggestion to offer, and we may therefore conclude that he accepts the old "playground theory." R. L.

## *THE COSMIC ORIGIN OF MOLDAVITE.*

MUCH attention has recently been devoted by Austrian and Bohemian geologists to the solution of an interesting question, that of the origin of those peculiar glassy bodies which are known collectively as moldavite or bouteillenstein. It has been considered by some authors that these fragments are to be looked upon as representing the relics of prehistoric glass-manufacture; but, as recently noted in the columns of NATURE, Herr J. Bareš has lately brought forward experimental proofs to refute the theory of the artificial origin of moldavite glass. Additional stimulus has been given to the study of this problem by the recent enunciation of a

new theory. Dr. F. E. Suess has expressed the opinion that these glassy fragments bear strong analogy to meteorites, and that they are in reality, like the latter, aerolites. In support of this view, in addition to other arguments, he lays special stress on the nature of the peculiar, though varying, surface sculpture of bouteillenstein, a sculpture not consistent with any theory of mechanical transport in water. Prof. Rzehak, however, has opposed this hypothesis of a cosmic origin, and brings forward arguments for its refutation. This author rather inclines towards the theory of an artificial origin; but Bareš, by experiments above referred to, applied a process of elimination to the various theories put forward for the terrestrial origin of the glass, and finally considered that of Dr. Suess to be most probably the correct one. A recent contribution to the literature of this subject is a short paper brought before the Böhmische Kaiser Franz-Josefs Akademie (Prague) by J. N. Woldrich last December. An abstract of this appears in the *Bulletin International* (dated 1898) issued by the Academy, and from the photographs illustrating that paper the accompanying figures have been selected for reproduction.

FIG. 4.

FIG. 8*a*.

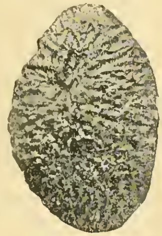

FIG. 6.

Herr Woldřich describes the surface markings of specimens in his own large collection, and points out the resemblance between certain of these Bohemian examples and the peculiar obsidian-bombs from Australia, described by Stelzner. Some of the Bohemian occurrences show, in fact, a hollow, bomb-like form. A fragment of such a specimen is represented in Fig. 8*a*. Figs. 4 and 6, photographed in natural size, show two characteristic types of sculpture, Fig. 4 exhibiting "finger impressions," and Fig. 6 a network of furrows, having in part a rough radial arrangement. The moldavite found both in northern and southern Bohemia occurs in sandy deposits which are regarded as belonging to either late Tertiary or early Diluvial time. Herr Woldřich considers that the known facts relating to moldavite and its distribution speak in favour of its extra-terrestrial origin, but that it is only known to occur in sandy deposits, whether in Europe or on other parts of the earth's surface, he regards as a striking circumstance.

## NOTES.

AT a meeting of the Glasgow University Court held on the 13th inst., Principal Story presiding, a petition for leave to retire from the chair of Natural Philosophy was presented from Lord Kelvin. The Court granted the leave asked, and accepted Lord Kelvin's resignation with deep regret. A remit was made to the Principal to prepare a minute to be signed by all the members of the Court, expressing their sense of the great loss that the University is now to sustain. Lord Kelvin has occupied the chair for fifty-three years.

DR. P. F. RAYMOND, the successor of Prof. Charcot in the chair of Nervous Diseases at the Saltpêtrière, has been elected a member of the Paris Academy of Medicine.

PROF. KLEIN proposes to spend two or three weeks in this country, so that, after the work of the Catalogue Conference is finished, he can have an opportunity of discussing, with our mathematicians and physicists, the plan and scope of the second part of the *Encyklopädie der Mathematischen Wissenschaften*, which deals with Applied Mathematics. The season for his visit is in some respects unfortunate, as being a holiday time; on the other hand, there is the advantage that those who are to be found at home will have plenty of leisure to devote to the discussion of the details of this great work.

THE death is announced, at the age of eighty-seven years, of the Right Rev. Charles Graves, Lord Bishop of Limerick, who in 1843 was appointed Erasmus Smith professor of pure mathematics at Trinity College, Dublin. His published work appeared for the most part in *Crelle's Mathematical Journal*, and many of his theorems are to be found in text-books on geometry. In 1841 he edited a translation, with considerable additions, of Chasles' "Memoirs on Cones and Spherical Conics." He was elected President of the Royal Irish Academy in 1861, and a Fellow of the Royal Society in 1880.

THE death is announced in the *Athenaeum* of Dr. Eugen Ritter von Lommel, Rector of the University and a member of the Academy of Sciences of Munich. He was the author of several works, including "Das Wesen des Lichts," "Wind und Wetter," and "Lexikon der Physik und Meteorologie."

THE negotiations which for some time past have been carried on between the Royal Geographical Society and the University of Oxford with a view to the establishment at Oxford of a fully-equipped school or institute of geography, for the use, not only of Oxford graduates and undergraduates, but of others who desire to avail themselves of such an opportunity, have come to a satisfactory conclusion, and the school will begin operations in October next, under the direction of Mr. H. J. Mackinder. The Royal Geographical Society is to contribute 400*l.* annually for five years out of the 800*l.* required, and the school will be under the supervision of a joint committee of representatives of the Society and the University. At a recent meeting of the committee, the staff was appointed, Mr. Mackinder being the head of the school, and dealing specially with historical geography; Mr. A. J. Herbertson has been appointed assistant to the Reader, and will deal with physical geography, cartography, and surveying; Mr. H. N. Dickson has been appointed Lecturer on Physical Geography; and Mr. G. B. Grundy will in 1899-1900 lecture on ancient geography. The work of the school will include a course of systematic instruction primarily intended for graduates and other advanced students, with classes, demonstrations, and practical work in physical geography, cartography, and surveying. Courses of lectures will also be given with special reference to the historical and scientific teaching of the University. The work will be carried on for five days each week during term. The lecture-room and laboratory will be in the Old Ashmolean

Museum, the upper floor of which is being fitted with the necessary appliances.

PARTICULARS have reached us of the autumn meeting of the Iron and Steel Institute, which, as has already been announced in NATURE, is to be held in Manchester from August 15 to 18 next. The following papers have been promised for reading :—On the constitution of steel, by Prof. E. D. Campbell ; on diffusion in steel, by F. W. Harbord and Thomas Twynam ; on the magnetic concentration of iron ore, by H. C. McNeill ; on India as a centre for steel manufacture, by Major R. H. Mahon, R.A. ; on pig iron fractures and their value in foundry practice, by J. W. Miller ; on practical microscopic analysis for use in the steel industries, by C. H. Ridsdale ; on the relation between the structure of steel and its thermal and mechanical treatment, by Albert Sauveur ; on the present position of the solution theory of carburised iron, by Dr. A. Stansfield ; on the iron industry in the territory of his Highness the Nizam, by Shamsul Ulama Syed Ali Bilgrami ; on a new casting machine for blast furnaces, by R. Hanbury Wainford ; on the utilisation of powdered iron ore, by Prof. J. Wiborgh. In the outline programme, just issued, full particulars are given of a number of excursions for which arrangements have been made.

THE summer meeting of the Institution of Naval Architects, which is taking place this week at Newcastle-upon-Tyne, was opened on Tuesday, when papers were read by Sir Andrew Noble (on "The Rise and Progress of Rifled Naval Artillery"), Dr. F. Elgar (on "The Distribution of Pressure over the Bottom of a Ship in Dock, and over the Dock Blocks"), and Mr. Nelson Foley (on "A New System of Forced Draught").

A CONFERENCE was held at the Home Office on Tuesday with some of the principal pottery manufacturers, in reference to the report by Prof. T. E. Thorpe and Dr. T. Oliver on the employment of compounds of lead in the manufacture of pottery.

*Science* states that a laboratory for the physical analysis of soils has been established by the Maryland Geological Survey. A full outfit of apparatus has been installed, and work will be engaged in during the coming year upon the soils of Maryland, in conjunction with the geological surveying of the same area. The Survey has also recently had constructed an elaborate calorimeter for the determination of the calorific power of coal, preparatory to the investigations of the coal formations of Maryland, an exhaustive report on which is promised for an early date.

THE Magnetic Observatory at Vienna having had to be discontinued in consequence of the electric tramways and electric light wires, Prof. Pernter has submitted to the Austrian Government a plan for a new observatory to be situated at some distance from Vienna, and to be provided with instruments of the latest construction.

ACCORDING to the *Pharmaceutical Journal*, a committee has been formed in France to organise a public subscription in aid of scientific research, with a view to the discovery of new methods of treatment for infectious and contagious diseases. That the need is pressing will be seen when it is stated that France loses every year by these diseases two hundred and forty thousand victims, nearly double the number of lives lost in the Franco-Prussian war of 1870. Out of this total, tuberculosis is responsible for 100,000 deaths ; typhoid fever and other contagious diseases, such as small-pox, measles, scarlatina, whooping-cough, diphtheria, and puerperal fever for 64,000, without speaking of the ravages caused at long intervals by cholera and plague.

THE committee appointed to inquire into the use of preservatives and colouring matters in food held their first meeting on Monday, when there were present Sir Herbert Maxwell, M.P. (in the chair), Dr. Timbrell Bulstrode, Dr. Tunnicliffe, and Mr. C. J. Huddart (secretary). The terms of reference to the committee were under discussion, and certain preliminary matters were disposed of, a second meeting being fixed for early in August to complete arrangements for the carrying out during the hot weather of necessary experiments in relation to the use of preservatives and colouring matters in one and another class of food, and to settle the scope of the evidence to be taken when the committee reassemble in October next.

THE Liverpool expedition for the study of malaria in Sierra Leone, to which attention has already been called in these columns, will sail on July 29. In addition to Major Ross and Dr. Annett, each of the Liverpool School of Tropical Diseases, the expedition will include Mr. E. E. Austen, of the British Museum (Natural History), and Dr. S. Van Neck, official delegate of the Belgian Government. The School of Tropical Diseases has recently been in communication with the various Government departments concerned with regard to the forthcoming research. On July 1 the Colonial Office wrote that Mr. Chamberlain had learned with great satisfaction that the expedition of the Liverpool School was being sent, and that he appreciated the energy and public spirit shown by the Committee of the School in the matter. Mr. Chamberlain also stated that the local authorities at Sierra Leone will be instructed to give every facility to the work of the expedition.

THE Vienna correspondent of the *Times*, telegraphing to that paper on July 14, says the renewed experiments by Prof. Tuma and a number of officers of the Vienna garrison to test the possibility of wireless telegraphy between two balloons were attended with a certain degree of success. A balloon held captive at a height of 150 metres served in place of the mast used in the Marconi experiments, being connected with the despatching instruments on the ground by a copper wire. The second free balloon carried a receiving instrument and a wire which hung loose 20 metres below the car. In these conditions it was found possible to communicate with the three officers in the free balloon, who signalled with flags that they had received and understood the telegraphic messages. These signals were observed at an estimated height of 1600 metres and a distance of about 10 kilometres from the despatching station. Owing to the size and weight of the accumulators and the great danger of bringing them into close proximity to a large volume of explosive gas, it is thus far impossible to telegraph from a balloon to the ground or from one balloon to another. On the return of the officers to Vienna a comparison will be made between the detailed particulars noted by them and the report of the actual messages despatched.

THE Liverpool Section of the Society of Chemical Industry proposes, with the approval of the Council, to perpetuate the memory of the late Dr. Ferdinand Hurter, especially his great services to applied chemistry, by instituting a memorial lecture to be given every second year on some subject connected with applied chemistry. The lecturer will be chosen by the Liverpool Section of the Society, and it is proposed to collect a sum of 300*l.*, which it is supposed will be sufficient for the endowment.

ON the afternoon of Saturday, July 8, a marble bust of the late Prof. William Rutherford, F.R.S., was unveiled in the Physiology Class-room of the University of Edinburgh by Principal Sir William Muir, in the presence of, among others, Sir William Turner, Prof. T. R. Fraser, Prof. Crum Brown, Prof. Hunter Stewart, Dr. Clouston, and Dr. E. W. W. Carlier. The Lord Provost of Edinburgh and Prof. Schäfer sent apologies for absence. The bust, which is by Mr. John Hutchinson, was

subscribed for by past and present members of the class of physiology. It bears the following inscription on the pedestal:—"In piam memoriam Gulielmi Rutherford, M.D., F.R.S., in Universitate Academica Edinburgensi, ab anno MDCCCLXXIV. ad annum MDCCCXCIX., Physiologiæ Professoris hanc effigiem posuerunt discipuli eius Universitatis huius cives. A.D. MDCCCXCIX."

Sir John Wolfe Barry, K.C.B., F.R.S., has been elected by the Council of the Society of Arts chairman for the ensuing year.

The fourth International Congress of Psychology will be held in Paris from August 20–25, 1900. The organisation is left to the French members, and the following are the officers: President, Th. Ribot, professor of experimental and comparative psychology in the Collège de France; Vice-President, Charles Richet, professor of physiology in the Paris Faculty of Medicine; General Secretary, Pierre Janet, Director of the Laboratory of Psychology in the Collège de France. The seven Sections and the Presidents are as follows: (1) Psychology in its relations to physiology and anatomy, Prof. Matthias Duval; (2) Introspective psychology and its relations to philosophy, Prof. G. Séailles; (3) Experimental psychology and psycho-physics, M. A. Binet; (4) Pathological psychology and psychiatrie, Dr. Magnan; (5) Psychology of hypnotism and related questions, Dr. Bernheim; (6) Social and criminal psychology, M. Tarde; (7) Comparative psychology and anthropology, Prof. Yves Delage. Those wishing to attend the congress should apply to the Secretary, and those wishing to present papers should forward abstracts not later than January 1 next.

A combined meeting of the German and Viennese Anthropological Societies is to be held at Lindau from September 4 to 7 of the present year.

An expedition to determine the geological and mineralogical features of the almost unknown region lying between Buffalo Hump, in Idaho County, Idaho, and the Nez Perce Pass, in the Bitter Root range, has been organised and equipped by Colonel W. S. Brackett, of Peoria, Ill. The party numbers twelve men, all of whom are stated to be experienced mountaineers.

Reports from Vancouver, British Columbia, announce the ascent for the first time of Mount Morrison, the highest mountain in Formosa, by Stoepel, the explorer of the Pic of Orizaba n Mexico.

Dr. D. J. Leech, professor of materia medica and therapeutics at the Owens College, Manchester, will deliver the address inaugurating the winter session of the Pharmaceutical Society on October 2, and on the occasion the Society's Hanbury medal will be presented to Prof. Albert Ladenburg, of Breslau, for his researches into the chemistry of the atropine alkaloids.

The "Board of Estimate and Appointment" for the City of New York has set aside 63,000 dollars for the zoological garden in Bronx Park. It is also proposed to raise the appropriation for the American Museum of Natural History from 90,000 to 130,000 dollars annually.

An appeal has recently been made in the Manchester press, by the President and Secretary of the Manchester Literary and Philosophical Society, for help in restoring the tomb of Dalton the chemist. The appeal is made "to those residents of Manchester, chemists and others, who are interested in the work and fame of John Dalton." It appears that the funds of the Society cannot be used for the purpose, but the Council "have felt that the continued neglect of the resting-place of one of Manchester's greatest worthies would be a scandal and a discredit." The sum of 75*l.* in all is the amount endeavoured to be raised, it being thought that the interest on the sum remaining after the payment of present repairs has been made will suffice for keeping the tomb in repair.

Mr. Griesbach states in the annual report of the Geological Department of India that last year a find of copper and gold was reported near the village of Rohera, a station on the Rajputana-Malwa Railway, in Sirohi territory. The place had evidently been worked for copper in ancient times, and to a considerable extent, as may be seen from the heaps of copper slag in the vicinity. The old mine had, however, not been sufficiently excavated at the time of the Director's visit to enable him to judge of the extent of the deposit.

A considerable amount of attention has, says the *Journal of the Society of Arts*, been given in France to what may be termed general agricultural education. Agricultural teaching, of a more or less rudimentary order, has been made obligatory at elementary schools, and a small garden for practical illustration has been attached to many of these institutions in rural districts, and the instruction thus given has, it is said, produced most beneficial results. The general instruction is given by departmental professors and special professors, whose duties may be divided into two distinct sections: (1) general instruction of adults—in the service of the Ministry of Agriculture; (2) teaching in the normal schools—in the service of the Ministry of Public Instruction. The tuition for adults takes the form of lectures, delivered in different parts of the department. The lectures are intended to enlighten landed proprietors, farmers, and others as to the best agricultural methods, the applications which can be made of scientific discoveries, &c.; in a word, to assist them in reaping the greatest possible profit from their land. The subjects treated naturally vary greatly according to the needs of the population of each department; the lectures, however, possess one characteristic in common, they are of an essentially "popular" type. The lecturer also, at the close of each lecture, places himself at the disposal of his audience, with the object of advising them individually regarding special questions, and of elucidating any points touched upon in his discourse which they may have failed to grasp. The most powerful aids to this class of teaching are found in the "experimental" and "demonstration" fields. Attention is also called to the agricultural stations and laboratories of the country, which, though not properly coming within the sphere of educational establishments, render considerable service to the agricultural population.

According to the *National Geographic Magazine*, forecasts for forty-eight hours in advance, for all States east of the Rocky Mountains, were, for the first time in the history of the Weather Bureau, regularly issued from Washington each night during April of the present year.

Orders issued by the Government of India to civil surgeons with entomological proclivities require them "to make collections of mosquitoes and other flies that bite men or animals, in accordance with the instructions contained in Prof. Ray Lankester's pamphlet," with a view of determining the possible connection of malaria with mosquitoes. For the general detructions of mosquitoes several methods have, says the Indian correspondent of the *Lancet*, been tried. In many places the engineer has been successful by draining the marshy areas. In others the use of kerosene by throwing it into the water where it forms a film on the surface has prevented the developing larvæ from reaching the air, and has thus brought about their destruction. A more recent experiment has been the employment of permanganate of potash, which is said to kill the insect in all stages of its development. As this chemical has also been

largely employed for purifying the water of doubtful wells, and especially with the view of protecting against the cholera bacillus, it would seem particularly applicable for use in India.

THE *Times* of Monday published a very interesting account of a visit paid by Dr. Karl Peters last April to some ruins near the river Muira, a southern tributary of the Zambesi, in Portuguese territory, nearly opposite Shupanga. The explorer made his journey in consequence of a passage in the *Atlas Historique*, which is to the effect that half a day's journey from the river Mansoro is the fort of Massapa, and near this is the great mountain of Fura, very rich in gold, in which are Cyclopean ruins. It was to find these ruins that Dr. Peters, accompanied by Mr. Leonard Puzey and Mr. Ernest Gramann, journeyed from the Zambesi. After recounting incidents of the journey, the writer says the decisive discovery for the exploration was made by Mr. Puzey on April 20. The ruins are situated on the hill which runs parallel to Mount Peters, and are about two miles distant from Inja-ka-Fura. Dr. Peters' description of his discovery is as follows: "We discovered . . . another ground-wall which had undoubtedly been a part of a building, maybe a temple, maybe a storehouse. This wall had been worked into the natural rock, which here forms a sort of flat floor. The stones of this ground-wall, samples of which I have sent to London, are heart-shaped, and are worked with a pick, so that the description in our old report saying the stones were not worked with a pick apparently only applies to the outer walls. Perhaps the author never took the trouble to visit one of the ruins. I laid bare a part of this ground-wall on the top, but gave up further digging because I was afraid that my clumsy workmen might do harm to the remains. They have, indeed, already destroyed part of the ground-wall. The stones of the wall are a pseudomorph sandstone, while the rock into which they are worked is quartzitic slate. The whole of the ruin is built after the general ancient Semitic pattern. The Cyclopean wall skirts the hill about halfway between the bottom and the top; on the top the buildings, the hoarding-place, and likely the temple were standing. The remains of a ground-wall along the edge of the top lead me to believe that a second wall formerly ran round the platform itself. To explore the ruin properly it will be necessary to send a scientific expedition with a proper outfit for such excavations. The débris have to be removed, and this I am sure will take a considerable time. Why the old conquerors chose this spot for their fort is easy to see. The Muira touches the bottom of the hill, so water was handy. A second river we have discovered at the back of the ruin. From the top they had an outlook over the wide plain before them, while they had the bulk of the Fura massive at their back. From their fort they commanded the plain as well as the mountain. I have called the hill on which the ruin stands after its discoverer 'Puzey Hill.' Mr. Puzey some days later found a second ruin west-north-west of the first on another head of the same ridge looking over the plain in the same direction. I am certain we shall find still more of these Cyclopean buildings when our time, which now is otherwise occupied, permits of a more extended exploration."

THE *British Central Africa Gazette* for May 24, which has just reached us, says "from time to time it has been rumoured that giraffes existed in British Central Africa, on the Loangwa River, but, although that river valley has been frequently visited during the last ten years by Europeans, no authentic information on the point has ever been obtained. Last month, however, a giraffe was shot on the east bank of the Loangwa in the Marimba district by a European prospector, and its skin (incomplete) sent in to Captain Chichester in Mpezeni's country. The hinder half of the skin is being sent to the British Museum, and it is hoped that a complete specimen may be now obtained. The existence of giraffe in Marimba is remarkable: the area in which they are found is extremely restricted, and their number appears to be very few. The one shot, however, was in a herd of about thirty-five. The nearest country north of Marimba in which giraffe are known to exist is north of Mareres, where the Elton-Cotterill Expedition met with them (many years ago). To the south, Matabeleland is the nearest giraffe country."

THE same number of the *Gazette* states that there seems to be no further decrease in the number of elephants still existing in the Protectorate; indeed, the natives round about Domwe have been complaining to the Acting Collector of the damage done in their food plantations by these animals.

IN the Johns Hopkins University *Circulars* for June 1899 a number of notes from the physical laboratory are published under the editorship of Prof. Joseph S. Ames. These comprise a short paper on the effect of temperature, pressure, and used solutions on the deposit of silver voltameters, by J. F. Merrill; notes on the energy-spectrum of a black body, and on the absorption of ice in the ultra-red, by F. A. Saunders; on the Zeeman effect, by H. M. Reese; on electric absorption in condensers, by L. M. Potts; on transference of heat in cooled metals, and on a method of measuring the frequency of alternating currents, by Carl Kinsley. A list of publications in the department of physics, by those who are now or who have been members of the University, is appended. This list, which represents roughly a year's work, occupies three columns, and includes over ninety works and papers by sixty authors. Similar notes and lists from the department of history and politics also appear in the same number, under the editorship of Prof. Herbert B. Adams.

THE *Berichte der Naturforschenden Gesellschaft* of Freiburg (Baden) contains several papers of interest to physicists. Kathode and Röntgen rays form the subject of a discourse by L. Zehnder, who deals somewhat fully with the theory of fluorescence; Prof. F. Himstedt describes apparatus for illustrating lecture experiments on Hertzian waves and on Marconi's telegraphy, and also writes on point-discharges in high-frequency currents. Of biological interest in the same number are Prof. G. Steinmann's notes on the formation of dark pigment in mollusca, and on *Boueina*—a genus of fossil algæ, and August Grüber's note on green *Amoebae*.

A GOOD work is being done in Italy by the "Valle di Pompei," an institution in the province of Naples for rescuing and educating the children of prisoners and criminals. Apart from the philanthropic aspect of this undertaking, the *Report* contains statistics of interest to anthropologists, criminologists, and those who make a study of heredity. It would appear that under the salutary influence of their environment the children of the worst criminals often take a prominent place in the matter of good conduct and diligence.

THE U.S. Weather Bureau has issued a very useful pamphlet (*Bulletin* No. 26) entitled "Lightning and the electricity of the air," by A. G. McAdie and A. J. Henry. The work is divided into two parts: Part 1 deals with the electrification of the atmosphere and the best methods of protecting life and property from lightning, being to a large extent a revision of *Bulletin* No. 15—"Protection from lightning." Part 2 gives statistics of actual losses of life and property sustained in the United States during 1898. The principal facts of the paper are drawn from articles by the authors in various magazines, with the object of furnishing information of practical value generally, especially to those who may have occasion to seek protection from lightning. The work contains interesting particulars relating to the electrical potential of the upper air, as manifested by kite experiments and auroral displays.

THE Pilot Chart of the North Atlantic Ocean for July, issued by the Hydrographic Office of Washington, contains an article on tropical cyclonic storms or West India hurricanes which are prevalent at this season of the year. From a table showing the number of storms experienced between 1885 and 1898, it is seen that the greater number occur between August and October. The nature and mean path of the hurricanes are exhibited by a diagram. In its earlier stages, the centre of the path of the storm has a certain amount of westing, due to the general westward motion of the atmosphere in the low latitudes in which the storm originates, and the whirl is small, probably less than 100 miles in diameter, but its growth is rapid, so that in the middle and higher latitudes it may attain a diameter of 500 or even 1000 miles. The velocity of progression along the track of the disturbance reaches from twenty to thirty miles an hour in high latitudes, while the velocity of the whirl itself, in a direction against the hands of a watch, attains the force of a hurricane.

THE interesting and useful "Glossary of Popular Local and Old-fashioned Names of British Birds" contained in "A Dictionary of Bird Notes," by Mr. Charles Louis Hett, has been issued separately by Jackson, of Brigg.

THE additions to the Zoological Society's Gardens during the past week include a Bonnet Monkey (*Macacus sinicus*, ♂) from India, presented by Miss Nesta Bevan; a Black-faced Spider Monkey (*Ateles ater*) from Eastern Peru, presented by Mrs. K. E. Mackenzie; two Campbell's Monkeys (*Cercopithecus campbelli*, ♂ ♀) from West Africa, presented by Captain F. R. B. Parmeter; a Mozambique Monkey (*Cercopithecus pygerythrus*) from East Africa, an Arabian Gazelle (*Gazella arabica*) from Arabia, presented by Mr. B. T. Ffinch; two Common Foxes (*Canis vulpes*) from Russia, presented by Mr. A. H. Britten; an Arctic Fox (*Canis lagopus*) from Iceland, presented by Mr. M. Magnusson; five Common Hedgehogs (*Erinaceus europaeus*), European, presented by Mr. Geo. Long; three Chipping Squirrels (*Tamias striatus*) from North America, presented by the Rev. A. E. Tollemache; a Common Peafowl (*Pavo cristatus*, ♂) from India, presented by Miss A. S. Heldmann; two Climbing Anabas (*Anabas scandens*) from India, presented by Mr. P. Burford; two Rheas (*Rhea americana*, white var.) from Argentina, two Syrian Bulbuls (*Pycnonotus xanthopygos*) from Syria, an European Pond Tortoise (*Emys orbiculare*), European, deposited; two Rose-coloured Pastors (*Pastor roseus*), two Indian Mynahs (*Acridotheres ginginianus*) from India, two Bamboo Partridges (*Bambusicola thoracica*) from Northern China, two Lunulated Honey-eaters (*Melithreptes lunulatus*), two Pied Grallinas (*Grallina australis*), two Musky Lorikeets (*Glossopsittacus concinnus*) from Australia, purchased; a Japanese Deer (*Cervus sika*, ♀), born in the Gardens.

HOLMES' COMET 1899 *d* (1892 III.).—Prof. C. D. Perrine gives full details of his rediscovery of the comet in *Astr. Journal*, No. 465. It was found with the 36-inch refractor, using a power of 270. It appeared as a round nebulous mass about 30″ in diameter, with only a slight brightening at the centre. The conditions were good, the sky being very clear and the star images steady. The object was very faint, not brighter than 16 mag., and very difficult to observe, so that the probable error of observation of its place was larger than usual.

DYNAMICAL THEORY OF NEBULÆ.—In No. 465 of the *Astronomical Journal*, Dr. E. J. Wilczynski gives an extended explanation of a dynamical theory of ring and spiral nebulæ which he first brought forward in 1896 (*Astro.-Phys. Journal*, vol. iv p. 97, 1896). He starts with the assumption that the primordial nebula exists either as an assemblage of meteorites or as a gaseous mass obeying the laws of hydrodynamics. Then, in some unexplained way, each particle is to describe a circular orbit about the common centre of gravity, at which point there may or may not be a condensation. Such an arrangement is not necessarily stable, the limit depending on the relative ratios of the masses and distances of the individual particles, and the ratio of the mass of the central controlling body to its distance from the swarm. If these conditions allow stability the body may condense to a star, single or double. If the system be unstable, however, then on applying Kepler's third law to the revolving particles it is found that the inner members, owing to their greater angular velocity, constantly advance with respect to the outer ones, and after an interval the particles originally lying along a *radius* of the swarm will be drawn out into a spiral curve, as is actually the case in the bodies known as spiral nebulæ. According to this view, the *age* of a nebula would be to some extent indicated by the *number of its coils*, and the author gives an interesting suggestion that this might be investigated by a minute comparative examination of all photographs of spiral nebulæ of different dates. The paper concludes by indicating the possibility of determining the *law of rotation* of these bodies by a combination of spectroscopic and photometric observations.

THE NATAL OBSERVATORY.—The annual report of Mr. E. Nevil, Government Astronomer of the Natal Observatory at Durban, consists chiefly of the detailed meteorological observations made at the institution. The staff consists of the director, one senior astronomical assistant, one junior astronomical assistant, and one meteorological assistant. The astronomical equipment includes an 8-inch Grubb equatorial refractor, a 3-inch Troughton and Simms transit instrument, sidereal and mean time clocks, 3-inch portable equatorial refractor, and an automatic signal transmitter and recorder. Owing to a reduction in the vote to the observatory, much of the work has had to be put aside.

The system of time signals established over the Colony has been carried on without alteration, this being facilitated by the erection of new wires. Since the appointment of the astronomer in 1882 there has been no official residence, the computations, &c., having been mostly made in the open air.

This is at last to be remedied by the erection of a residence, all the fixtures, water supply, &c., however, being provided by the astronomer himself.

TEMPERATURE CHANGES IN YERKES OBJECT-GLASS.—Prof. Barnard has several times made series of measures with the large telescope to find if the changes produced in the instrument by variations in temperature were of sufficient amount to necessitate their consideration in delicate investigations. During the last year observations have been made of the focus at temperatures varying from −22° F. to +80° F., the range thus being 102° (*Astr. Journal*, No. 462). The means of the observations made on nineteen nights show a marked difference in the focus, and it was found that the object-glass shortened 0·26 inch more than the steel tube which carried it. Micrometric measures of the difference in declination between the stars *Atlas* and *Pleione* of the Pleiades showed a decrease of nearly 0″·2 (from 0″·676 during July–September to 0″·491 during January–February).

From the result of these experiments Prof. Barnard thinks that for exact work, such as parallax, with a large glass in a variable climate, these minute changes ought to be determined and taken into account.

In addition to these visual observations, careful determinations of the changes in the colour-curve during wide extremes of temperature are being carried on by Prof. Frost and Mr. Ellerman.

## *THE REASON FOR THE HISSING OF THE ELECTRIC ARC.*[1]

HISSING is one of the few phenomena connected with the electric arc with which every one is more or less familiar. In the old days the sudden, almost complete, extinction of the light of an arc-lamp, and the loud hiss accompanying its relighting, was so common an occurrence that it was supposed by the lay mind to form part and parcel of the working of the "electric light," and led to a lively prejudice against that light on the part of the public. In these days of enclosed arcs and of better constructed lamps, such little interludes are of far less frequent occurrence; but it is as important as ever, from a scientific point of view, to discover their origin, and even from the practical side anything which points to a remedy for this grave defect in arc-lighting cannot fail to be of interest.

The object of the present article is to explain the cause of hissing in direct current open arcs; that is to say, in arcs in which the current flows always in one direction, and to which the air has free access at every point.

a sound something like that of steam under pressure, issuing from a pipe. This sound is accompanied by a diminution of about ten volts in the P.D., or electric pressure between the carbons, and an increase in the current.

For the experiments on which the present article was based, three sets of electrical measurements were made, viz. measurements of the current, the P.D. between the carbons, and the length of the arc. Before each observation was made the current and length of arc were kept *rigorously* constant for a sufficient length of time for the carbons to take their characteristic shape for that particular current and length of arc, and long enough, therefore, for the P.D. to have become constant also. Such an arc is called a *normal* arc, as contrasted with one arrived at in a haphazard fashion by suddenly giving the current some particular value and the arc some particular length, and making observations without allowing time for the carbons to acquire their proper forms.

The carbons used were generally both *solid*, that is, neither had a soft core such as is usually given to the positive carbon when the arc is employed for lighting purposes, and they were,

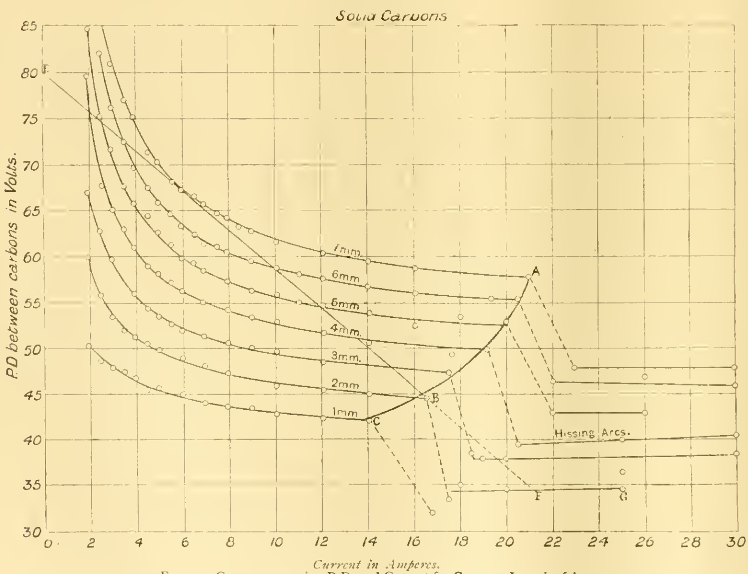

FIG. 1.—Curves connecting P.D. and Current for Constant Length of Arc.

Carbons:—Positive, 11 mm.; Negative, 9 mm.

There are other ways in which a change taking place in the arc may manifest itself, in addition to giving out sounds of various kinds or by becoming silent. For example, there may be changes in its electrical measurements, or an alteration in the appearance of the crater, the arc, and the carbons.

The sounds given out by the *direct current open* arc are many and various, but only two seem to possess much significance—the hum and the hiss—and the causes of these are evidently connected with one another, for the hum never occurs except when the arc is on the point of hissing or has just been hissing, although it is quite possible to make an arc hiss and become silent again without any hum being heard either before or after.

The hum is a distinct musical note, which is often quite low to start with, and gets higher and higher, till it finally rises to a shriek, and then the arc breaks into a loud hiss, giving forth

[1] Based on a paper read before the Institution of Electrical Engineers by Mrs. W. E. Ayrton.

as usual, placed vertically over one another with the positive carbon on top.

Some of the results of these experiments are given in Fig. 1, in which the curves connect the P.D. between the carbons with the current, for various constant lengths of arc. Starting from the left, each curve goes smoothly on its way, as the current increases, till a certain point is reached, when it suddenly breaks down, and is continued in a straight line far below and to the right of its own lowest point. The break-down occurs when the current has such a value that the arc can no longer remain silent. The dotted lines, which join the *curves* for silent arcs to the *straight lines* for hissing arcs of the same length, indicate ranges of current that will not flow through the particular length of arc indicated at all if the arc is normal with the arrangement of the circuit existing when the experiments were made.

An examination of these curves shows that with the carbons used, and with the *normal* arc, the following results are met with:

(1) When the length of the arc is constant and the arc is silent, it may be made to hiss by increasing the current sufficiently.

OPEN ARCS.

*Positive Carbon Cored.*

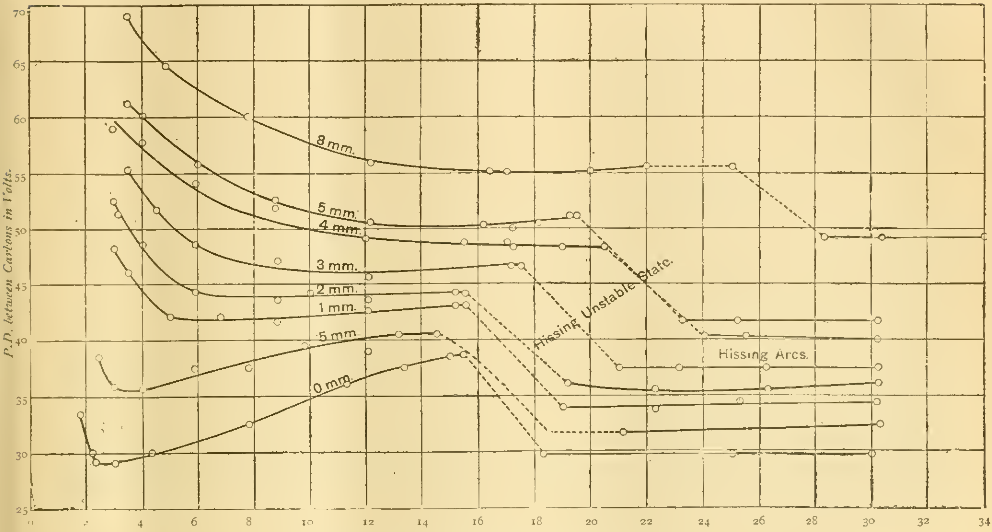

FIG. 2.—Curves connecting P D. and Current for Constant Lengths of Arc. Carbons:—Positive, 9 mm. Cored.; Negative, 8 mm. Solid.

(2) When the current is constant and the arc is silent, *shortening* the arc will make it hiss.

(3) The largest current that will maintain a *silent* arc is greater the longer the arc.

OPEN ARCS.

*Positive Carbon Cored.*

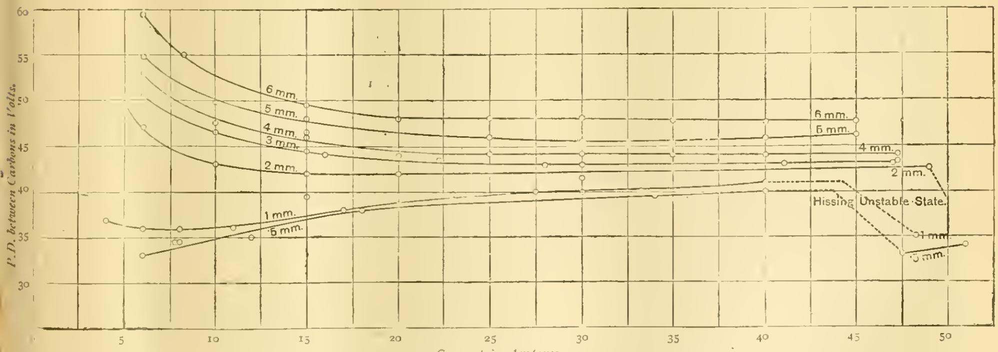

FIG. 3.—Curves connecting P.D and Current for Constant Lengths of Arc Carbons:—Positive, 18 mm. Cored.; Negative, 15 mm. Solid.

(4) When the arc begins to hiss, the P.D. suddenly falls about 10 volts and the current suddenly rises two or three amperes.

(5) For the hissing arc the P.D. is constant for a given length of arc, whatever the current.

It was Niaudet (*La Lumière Electrique*, 1881, vol. iii. p. 287) who, in 1881, first observed the fall of about 10 volts in the P.D. between the carbons at the moment hissing began, and, although perhaps there is even yet a lingering notion that it is only when an arc is short that it can hiss, I find that as far back as 1889 Luggin (*Wien Sitzungsberichte*, 1889, vol. xlvii. p. 118) showed that, however long an arc might be, it would still hiss were the current increased sufficiently.

At the Congress at Chicago in 1893 Prof. Ayrton (*The Electrician*, 1895, vol. xxxiv. pp. 336–7) first drew attention to the region of instability indicated by the dotted portions of the curves. At the same time he pointed out in Fig. 2, shown at Chicago, that whether the P.D. was descending as the current increased for, say, a 4 mm. arc, or was ascending for, say, a 0·5 mm. arc, it became quite constant for wide variations of current with a hissing arc.

And, lastly, by a comparison of Fig. 2 with Fig. 3 he brought out the fact that the largest current that would flow silently with any given length of arc was increased by using thicker carbons; for the carbons in Fig. 3 have about twice the diameter of those in Fig. 2, and while the largest silent current for, say, the 2 mm. arc in Fig. 2 is 15·5 amperes, that for the same length of arc in Fig. 3 is about 49 amperes, or more than three times as great.

Returning now to the subject of the dotted lines in Figs. 1, 2 and 3, it is plain that these divide the curves into two perfectly separate parts, governed by different laws. For to the left of the dotted part the lines are all curved, and curved differently according as *solid* positive carbons are used as in Fig. 1, or *cored* as in Figs. 2 and 3, showing that with silent arcs the P.D. varies as the current varies, and that the law of variation is different with solid and cored carbons. To the right, on the other hand, the lines are all straight, and more or less parallel to the axis of current, whether the positive carbon is solid or cored, showing that with *hissing* arcs the P.D. is the same for a given length of arc and a given pair of carbons, *whatever* current is flowing, and that this law is true whether the carbons be cored or solid. In fact, when the arc begins to hiss some complete and sudden break down appears to occur, upsetting all the laws that have governed it while it was silent, and making cored and solid carbons behave alike.

Thus, our subject divides itself quite naturally into two distinct portions, the one dealing with the arc when the break-down is imminent, but before it has actually occurred—dealing, that is to say, with the points at which the current is the largest that will flow silently—the *hissing points* as I shall call them; and the other dealing with the arc after the break-down has occurred, and when, therefore, the arc is really hissing.

An examination of Fig. 1 shows that the hissing points lie well on the curve A B C; that curve may, therefore, be taken to embody the laws connecting the P.D. between the carbons, the current, and the length of the arc, at the *hissing points*, for at least all those lengths of arc given by the curves in Fig. 1. The most important of these laws concerns the current at the *hissing point*, the largest *silent* current.

It is quite plain, from Fig. 1, that although this current increases as the length of the arc increases, yet it does not increase at the same rate as the length of the arc. For each millimetre added to the length of the arc involves a smaller and smaller addition to the largest silent current; so that finally a current must be reached which will not increase appreciably however much the arc is lengthened, always supposing that the law continues to hold for such long arcs. Hence, on this supposition, *for each pair of carbons the current that will sustain a normal silent arc has a maximum value, and any current greater than this will make the arc hiss, however long it may be.*

Other laws concerning the arc when on the point of hissing and when actually hissing can be deduced directly from Figs. 1, 2 and 3, but as these do not bear directly on the *cause* of hissing, the mathematical proofs of them may with advantage be omitted from the present article. Some of these laws may, however, be summed up as follows:—

If V be the P.D. in volts between the carbons at the hissing point for an arc of $l$ millimetres, and if V′ be the constant P.D. between the carbons for a hissing arc of the same length, then

$$V = 40{\cdot}05 + 2{\cdot}49\, l,$$
$$V' = 29{\cdot}25 + 2{\cdot}75\, l,$$

and consequently

$$V - V' = 10{\cdot}8 - 0{\cdot}26\, l,$$

which shows that *the longer the arc the less is the P.D. between the carbons diminished when it changes from silence to hissing.*

The numerical coefficients in the above equations naturally refer only to the carbons I used in my experiments, but the *laws* expressed by the equations must be true for *all* direct current open arcs of lengths not differing very greatly from those I used, and burning between solid carbons.

From Fig. 1 it might be supposed that, given the length of the arc, the increase of current that abruptly occurs on the arc starting hissing was as definite for that length of arc as the diminution in the P.D. And this, for a long time, I imagined to be the case. But while trying to find out what law connected the smallest hissing current with the length of the arc, I saw that the value of that current really depended on the circuit *outside* the arc. I found, in fact, that when the largest silent current for any length of arc changes to the smallest hissing current for the *same* length of arc, the value of that smallest hissing current depends on the E.M.F. of the dynamo *only*. The smaller that E.M.F. is, the greater will be the smallest hissing current for any given length of arc, while if the E.M.F. of the dynamo could be made infinite, the smallest hissing current and the largest silent current would be equal; that is to say, when the arc began to hiss the P.D. between the carbons would drop, but the current would remain quite unchanged.

Thus it is possible, by choosing suitable E.M.F.s, to make the sudden smallest hissing current have any value greater than that of the largest silent current for the same length of arc.

In 1889 Luggin found, by measuring the fall of potential between each carbon and the arc, that the principal part of the diminution of P.D. caused by hissing took place at the junction of the positive carbon and the arc. Some experiments of the same sort that I made about three years ago, using arcs varying between 1 mm. and 6 mm., gave the same result.

For the lengths of arc dealt with, I found that hissing caused a mean fall of about 9·7 volts in the total P.D. between the carbons, and a mean fall of about 6·3 volts in the P.D. between the positive carbon and the arc. Hence of the whole diminution of the P.D. between the carbons caused by hissing, about two-thirds took place at the junction of the positive carbon and the arc.

Further, my experiments showed that very little of the remainder of the diminution, if any, was due to a diminished fall in the P.D. between the arc and the negative carbon; therefore this remaining diminution must be attributed to a lowering of the resistance of the arc itself. We may sum up these results as follows:—

*Of the total diminution of the P.D. between the carbons caused by hissing, about two-thirds takes place at the junction of the positive carbon and the arc, and the remaining third seems to be due to a lowering of the resistance of the arc itself.*

We now pass from the consideration of the electrical measurements of the arc to the appearance of the crater, arc, and carbons.

Every alteration of the current and of the distance between the carbons naturally produces a corresponding modification of all parts of the arc, but until the value of the current attains a certain magnitude, which depends only on the length of the arc with a given pair of carbons, this change is one of degree merely, and not of character. A greater current simply produces a larger crater, a larger arc, and longer points to the carbons. When the special current is reached, however, a change, which is no longer simply one of degree, takes place in that white-hot depression at the end of the positive carbon from which most of the light of the arc is derived—the crater, as it is called. Instead of presenting a uniformly bright surface to the eye, this becomes partly covered with what appear to be alternately bright and dark bands, sometimes radial like the spokes of a wheel, sometimes in one or more sets of concentric circles, sometimes oscillating, sometimes rotating round different centres in opposite directions. The directions of rotation or oscillation and whole positions of the images change continually, and the motion grows faster and faster as the current is increased.

When the current is so much increased that the motion becomes too fast for the eye to detect, the arc begins to hum, and then, as Mr. Trotter (*Proc. Roy. Soc.*, vol. lvi. p. 262) first showed in 1894, it rotates at the rate of from 50 to 450 revolutions per second.

As soon as hissing begins the whole appearance of the crater changes again; a sort of cloud seems to draw in round a part of it, moving from the outer edge inwards, and varying continually in shape and position. Sometimes but one bright spot is left, sometimes several, but always the surface is divided into bright and dull parts, giving it a mottled appearance, as is slightly indicated in (*b*) Fig. 4. If, then, the current be diminished, so that the arc becomes silent again, the whole

surface of the crater grows dark for an instant, then brightens in spots, and finally becomes bright again all over.

The vaporous arc itself undergoes fewer modifications; it preserves the ordinary characteristics of the silent arc while rotating wheels hold possession of the crater, but, when humming begins, a green light is seen to issue from the crater, and with hissing this becomes enlarged and intensified, till the whole centre of the purple core is occupied by a brilliant greenish-blue light, as is indicated in Fig. 5.

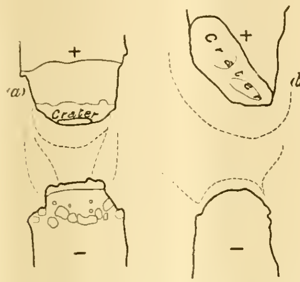

FIG. 4.—Carbons: Positive, 9 mm Cored; Negative, 8 mm Solid. Length of Arc. (a) 5 mm., (b) 8 mm. Current (a) 3·5 amperes, (b) 34 amperes.

M. Blondel, whose accuracy of observation and originality in experiment have added so much to our knowledge of the arc, first mentioned a very curious fact about this vapour in 1893 (*The Electrician*, 1893, vol. xxxii. p. 170). He noticed that, while the arc was silent, the vapour was quite transparent, so that, when viewed at a proper angle, the crater could be seen through it perfectly; but that, as soon as hissing began, the vapour became so opaque as to completely hide the crater.

In any case, however, M. Blondel's theory of a change from vapour to solid particles in the arc when hissing begins seems to me to be hardly tenable, if only for the following reason. Whenever we put solid carbon into the arc, such, for instance, as a very thin carbon rod, it glows far more brilliantly than the surrounding vapour, and hence increases the luminosity of the arc. If, therefore,

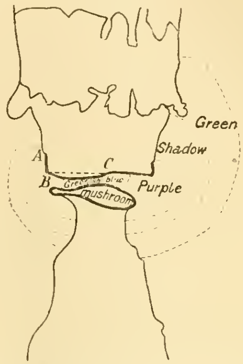

FIG. 5.—Carbons:—Positive, 11 mm. Solid; Negative, 9 mm. Solid. Length of Arc, 1·5 mm. Current, 28·5 amperes.

hissing is accompanied by a substitution of solid particles for the vapour of the arc, the luminosity of the arc should *increase* with hissing. But, M. Blondel mentions, in the same article, that the intrinsic brilliancy of the arc *diminishes* when hissing begins, hence the theory of a disruptive discharge of solid particles does not appear to cover the facts.

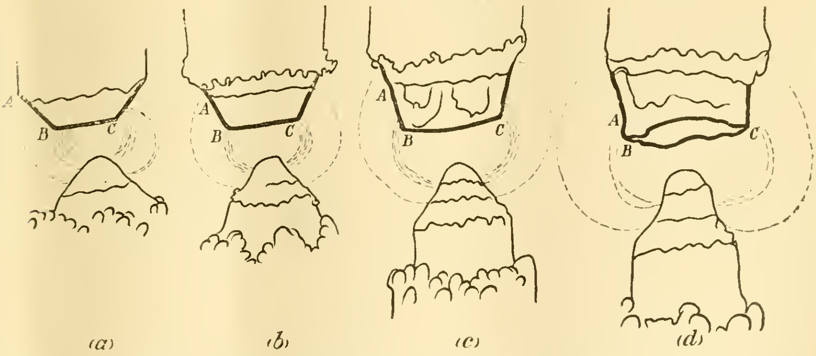

FIG. 6.—Carbons:—Positive, 11 mm. Solid; Negative, 9 mm. Solid. Length of Arc, 2 mm. Current, (a) 6 amperes, (b) 12 amperes, (c) 20 amperes, (d) 30 amperes.

M. Blondel believes that, when hissing begins, the gentle evaporation of the carbon of the crater, which feeds the column of vapour in the silent arc, gives place to a disruptive discharge of solid particles torn from the crater.

I have found the opacity of the hissing arc less complete and less invariable than M. Blondel, probably because my conditions were different from his. Indeed I have often been able to see the crater of a hissing arc through the vapour as clearly as if the arc were silent.

The *shape* of the arc also alters when hissing begins. When the arc is silent its shape is rounded, and it has an appearance of great stability; but as soon as hissing occurs, it seems suddenly to dart out from between the carbons and to become flattened out, as if under the influence of a centrifugal force acting at right angles to the common axis of the two carbons. In Fig. 5 and in (*d*) Fig. 6, this flattened appearance is well marked; and indeed these figures show that every part of the vaporous arc itself is involved in this flattening—the purple core,

the shadow round it, and the green aureole—as if they were all revolving with great rapidity round a common axis. And what more likely than that this should be the case, since, as has already been mentioned, the arc is revolving at the rate of 450 revolutions per second *at the moment that it starts hissing?*

As regards the carbons themselves, the only important modification of the *negative* carbon that appears to be due to hissing is the formation of the well-known "mushroom" at the end of that carbon with a *short* hissing arc. This mushroom, of which a good example is seen in Fig. 5, is well named, not only because of its shape, but also because of the rapidity of its growth, which is so great that, while it is forming, the carbons often have to be *separated*, instead of being *brought together*, to keep the length of the arc constant.

(*To be continued.*)

## HYBRIDISATION.[1]

OUR first duty, and a very pleasant one it is, is to welcome our foreign guests, our friends from across the sea, as I prefer to call them, to thank them for their presence here to-day, and to express a hope that their sojourn among us may be both agreeable and profitable. At the same time we regret that some, such as Dr. Focke, the historian of hybridisation, has not been able to preside over this meeting, as we had hoped he might have done. Nor can we at such a meeting do other than express our abiding regret at the loss, though at an advanced age, of the great hybridiser Charles Naudin.

Our next duty is to thank the Council of the Royal Horticultural Society for this opportunity of meeting once more in these time-honoured gardens to discuss what I venture to think is one of the, if not the most, important subject in modern progressive experimental horticulture. I use the words progressive and experimental because I believe that the future of horticulture depends very greatly on well-directed experiment.

So far as the details of practical cultivation are concerned, we are not so much in advance of our forefathers. We have infinitely greater advantages, and we have made use of them, but if they had had them they would have done the same. We are able to bring to bear on our art not only the "resources of civilisation" to a degree impossible to our predecessors, but we can avail ourselves also of the teachings of science, and endeavour to apply them for the benefit of practical gardening. We are mere infants in this matter at present, and we can only dimly perceive the enormous strides that gardening will make when more fully guided and directed by scientific investigations. One object of this conference is to show that cultural excellence by itself will not secure progress, and to forward this progress by discussing the subject of cross-breeding and hybridisation in all their degrees, alike in their practical and in their scientific aspects.

To appreciate the importance of cross-breeding and hybridisation we have only to look round our gardens and our exhibition-tents, or to scan the catalogues of our nurserymen. Selection has done and is doing much for the improvement of our plants, but it is cross-breeding which has furnished us with the materials for selection.

A few years ago by the expression "new plants" we meant plants newly introduced from other countries, but, with the possible exception of orchids, the number of new plants of this description is now relatively few.

The "new plants" of the present day, like the roses, the chrysanthemums, the fuchsias, and so many others, are the products of the gardeners' skill. From peaches to potatoes, from peas to plums, from strawberries to savoys, the work of the cross-breeder is seen improving the quality and the quantity of our products, adapting them to different climates and conditions, hastening their production in spring, prolonging their duration in autumn.[2] Surely in these matters we have outdistanced our ancestors.

But let us not forget that they showed us the way. I do not propose to dilate on the share which Camerarius, Millington, Grew, Morland, and others, at the close of the seventeenth century had in definitely establishing the fact of sexuality in plants, but I do wish to emphasise the fact that it was by experiment, not by speculation, nor even by observation, that the fact was proved, and I do wish to show that our English gardeners and experimenters were even at that time quite aware of the importance of their discovery, and forestalled our Herbert and Darwin in the inferences they drew from it. In proof of which allow me to quote from a work of Richard Bradley, called "New Improvements of Planting and Gardening, both Philosophical and Practical," published in 1717, cap. ii. After alluding to the discovery of the method of the fertilisation of plants, he says (p. 22):—

"By this knowledge we may alter the property and taste of any *Fruit* by impregnating the one with the *Farina* of another of the same class; as, for example, a *Codlin* with a *Pearmain*, which will occasion the *Codlin* so impregnated to last a longer time than usual, and be of a sharper taste; or if the *Winter Fruits* should be fecundated with the *Dust* of the *Summer kinds*, they will decay before their usual Time; and it is from this accidental coupling of the *Farina* of one with the other, that in an *Orchard* where there is Variety of *Apples*, even the *Fruit* are gathered from the same *Tree* differ in their Flavour and Times of ripening; and, moreover, the *Seeds* of those Apples so generated, being changed by that Means from their Natural Qualities, will produce different kinds of Fruit if they are sown.

"'Tis from this accidental coupling that proceeds the numberless varieties of Fruits and Flowers which are raised every day from *Seed*. . . .

"Moreover, a curious Person may by this knowledge produce such rare kinds of *Plants* as have not yet been heard of, by making choice of two *Plants* for his Purpose, as are near alike in their Parts, but chiefly in their *Flowers* or *Seed* vessels; for example, the Carnation and Sweet William are in some respects alike, the *Farina* of the one will impregnate the other, and the *Seed* so enlivened will produce a *Plant* differing from either, as may now be seen in the garden of Mr. *Thomas Fairchild*, of *Hoxton*, a plant neither *Sweet William* nor *Carnation*, but resembling both equally, which was raised from the *seed* of a Carnation that had been impregnated by the *Farina* of the Sweet William."

Here we have the first record of an artificially-produced hybrid, and you will remark that this was more than forty years before Kolreuter began his elaborate series of experiments. Fairchild was the friend and associate of Philip Miller, and of a small knot of advanced thinkers and workers who banded themselves together into a "Society of Gardeners."

"He is mentioned," says Johnson in his "History of English Gardening," "throughout Bradley's works as a man of general information, and fond of scientific research, and in them are given many of his experiments to demonstrate the sexuality of plants, and their possession of a circulatory system. He was a commercial gardener at Hoxton, carrying on one of the largest trades as a nurseryman and florist that were then established. He was one of the largest English cultivators of a vineyard, of which he had one at Hoxton as late as 1722. He died in 1729, leaving funds for insuring the delivery of a sermon annually in the church of St. Leonard's, Shoreditch, on Whit Tuesday, 'On the wonderful works of God in the Creation; or On the certainty of the resurrection of the dead, proved by the certain changes of the animal and vegetable parts of the creation.'"

Fairchild was thus not only the raiser of the first garden hybrid, but the originator of the flower services now popular in our churches.

We do not hear much of intentionally-raised hybrids from this time till that of Linnæus, in 1759 ("Amœn. Acad.," ed. Gilibert, vol. i. p. 212). The great Swedish naturalist, having observed in his garden a Tragopogon, apparently a hybrid between *T. pratensis* and *T. parvifolius*, set to work to ascertain whether this conjecture was correct. He placed pollen of *T. parvifolius* on to the stigmas of *T. pratensis*, obtained seed, and from this seed the hybrid was produced.

About the same time (that is, in 1760) Kolreuter began his elaborate experiments, but these were made with no practical aim, and thus for a time suffered unmerited oblivion.

Some years after, the President of this Society, Thomas

[1] Substance of the address by Dr. Maxwell T. Masters, F.R.S., delivered on opening the proceedings of the International Conference on "Hybridisation," Tuesday, July 11.

[2] See some interesting observations of MacFarlane on the period of flowering in hybrids as intermediate between that of the parents, *Gardeners' Chronicle*, June 20, 1891; and on the structure of hybrids, May 3, 1890.

Andrew Knight, and especially Dean Herbert, took up the work, with what splendid results you all know.

It is curious, however, to note that objections and prejudices arose from two sources. Many worthy people objected to the production of hybrids, on the ground that it was an impious interference with the laws of nature. To such an extent was this prejudice carried, that a former firm of nurserymen at Tooting, celebrated in their day for the culture, amongst other things, of heaths, in order to avoid wounding sensitive susceptibilities, exhibited as new species introduced from the Cape of Good Hope forms which had really been originated by cross-breeding in their own nurseries.

The best answer to this prejudice was supplied by Dean Herbert, whose orthodoxy was beyond suspicion. He, like Linnæus before him, had observed the existence of natural hybrids, and he set to work experimentally to prove the justness of his opinion. He succeeded in raising, as Engleheart has done since, many hybrid narcissi, such as he had seen wild in the Pyrenees, by means of artificial cross-breeding. If such forms exist in nature, there can be no impropriety in producing them by the art of the gardener.

In our own time, Reichenbach, judging from appearances, described as natural hybrids numerous orchids. Veitch and others have confirmed the conjecture by producing by artificial fertilisation the very same forms which the botanist described.

It remains only to speak of another respectable but mistaken prejudice that has existed against the extension of hybridisation. I am sorry to say this has been on the part of the botanists. It is not indeed altogether surprising that the botanists should have objected to the inconvenience and confusion introduced into their systems of classification by the introduction of hybrids and mongrels, and that they should object to hybrid species, and much more to hybrid genera; but it would be very unscientific to prefer the interests of our systems to the discovery of the truth.

I may mention two cases where scepticism still exists as to the real nature of certain plants: *Clematis jackmani* of our gardens, raised, as is alleged, by Mr. Jackman, of Woking (*Gardeners' Chronicle*, 1864, p. 825), was considered by M. Decaisne and M. Lavallée [1] to be a real Japanese species, and not a hybrid. This may be so, but there is no absolute impossibility in the conjecture that the Japanese plant and the cultivated plant originated in the same way. Again, Mr. Culverwell's supposed hybrid between the strawberry and the raspberry has been pronounced to be no hybrid, but to be *Rubus leesii*. But what, we may ask, is *Rubus leesii?* It appears to be a sterile form more closely allied to the raspberry than to the strawberry. Is it not at least possible that Mr. Culverwell has produced it artificially?

The days when "species" were deemed sacrosanct, and "systems" were considered "natural" have passed, and Darwin, just as Herbert did in another way, has taught us to welcome hybridisation as one means of ascertaining the true relationships of plants and the limitations of species and genera.

Darwin's researches and experiments on cross-fertilisation came as a revelation to many practical experimenters, and we recall with something akin to humiliation the fact that we had been for years exercising ourselves about the relative merits of "pin eyes" and "thrum eyes" in primroses, without ever perceiving the vast significance of these apparently trifling details of structure.

It would occupy too much time were I to dilate upon the labours of Gaertner, of Godron, of Naudin, of Naegeli, of Millardet, of Lord Penzance, of Engleheart, and many others. Nor need I do more than make a passing reference to the wonderful morphological results obtained by the successive crossings and inter-crossings of the tuberous begonias, changes so remarkable that a French botanist was even constrained to found a new genus, Lemoinea, so widely have they deviated from the typical begonias.

For scientific reasons, then, no less than for practical purposes, the study of cross-breeding is most important, and we welcome the opportunity that this conference affords of extending our knowledge of the life-history of plants, in full confidence that it will not only increase our stock of knowledge, but also enable us still further to apply it to the benefit of mankind.

## UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

DR. A. C. HOUSTON has been appointed Lecturer in Bacteriology at Bedford College, London, for Women.

Dr. W. WACE CARLIER, at present Lecturer on Experimental Physiology and Histology in the University of Edinburgh, has been appointed Professor of Physiology in Mason University College, Birmingham.

THE Royal Commissioners for the Exhibition of 1851 have approved the nomination by the University College of North Wales of Mr. Robert Duncombe Abell to a Science Research Scholarship of the value of 150*l.* a year. Mr. Abell is about to enter the University of Leipzig, where he proposes to engage in a special research under the direction of Prof. Wislicenus.

THE following appointments abroad may be noticed:—Dr. James Ewing to be professor of pathology in the Cornell University Medical College; Dr. Charles W. Wardner to be professor of physics in Williams College; Dr. H. G. Byers to be professor of chemistry in the State University of Washington; Dr. Alfred H. Seal to be professor of chemistry in Girard College, Philadelphia.

THE new buildings of the London Hospital Medical College were opened on Tuesday last. They occupy the site of the old chemical theatre and laboratory, and comprise the following rooms and departments. On the basement is the department of public health, containing a large museum, professors' room, class rooms, &c.; on the ground floor, the biological laboratory, class rooms, and the materia medica museum; on the first floor, the chemical theatre and laboratories, and the balance room; on the second floor, the physics laboratory, the chemical laboratory for the diploma in public health classes, the operative surgery room, and a large anatomy class room leading from the dissecting room. On the third floor is the bacteriological department, with general laboratory, research laboratories, class rooms for public health work, sterilising room, &c. Other portions of the building have thus been left for additional development, and advantage has been taken of this to provide special class rooms for students studying for the preliminary scientific, the intermediate M.B., London, and other examinations. Additions have also been made to the present physiological department, giving rooms for original research and for special class work for the higher examinations. For all these departments special teachers have already been appointed, who are devoting their entire time to the particular subjects that they have undertaken. The new buildings, with their fittings, will cost altogether not less than 10,000*l.*

## SCIENTIFIC SERIAL.

*Bollettino della Società Sismologica Italiana*, vol. v. No. 1, 1899–1900.—The rules of the Society and list of Fellows (forty-three national and ten foreign) are given.—Determination of the epicentre and time at the origin of earthquakes of unknown origin propagated along the earth's surface by means of four or five time-observations, by G. Costanzi. Equations for the above purposes are obtained on the supposition that the surface-velocity is constant.—Vesuvian notices (July–December 1898), by G. Mercalli. A monthly chronicle, with notes on the paroxysm of September, the central crater, and the excentric eruptive apparatus; illustrated by reproductions of two photographs.—Notices of the earthquakes observed in Italy (January 1–February 3, 1898), by G. Agamennone, the most important being the Ferrara earthquake of January 16, a distant earthquake on January 25, and the Asia Minor earthquake of January 29.

## SOCIETIES AND ACADEMIES.

### LONDON.

Royal Society, June 15.—"On the Application of Fourier's Double Integrals to Optical Problems." By Charles Godfrey, B.A.

The disturbance received at any point from a luminous body is a vector, varying with the time. It may be defined by its resolved parts along three rectangular axes; let $f(t)$ be one of these resolutes. In general $f(t)$ will not be a periodic function,

even when the light is approximately monochromatic. By Fourier's theorem of double integrals

$$f(t) = \int_0^\infty (C \cos ut + S \sin ut) \, du,$$

where

$$C = \frac{1}{\pi} \int_{-\infty}^{+\infty} f(v) \cos uv dv, \quad S = \frac{1}{\pi} \int_{-\infty}^{+\infty} f(v) \sin uv dv.$$

This is true provided $f(t)$ is subject to certain conditions, which are proved to be present in any physical problem. The object of the paper is to inquire whether the above theorem justifies us in regarding any plane-polarised plane light motion as equivalent to a combination of simple harmonic vibrations, with periods varying from 0 to $\infty$. The element of the integral suggests a vibration of amplitude $du \sqrt{C^2 + S^2}$, phase $\tan^{-1}\frac{S}{C}$, and period $\frac{2\pi}{u}$. It is proved that in certain very general cases such an interpretation is possible, notably in the case of "constant" light, such as presents a steady appearance.

This calculus enables us to discuss the width of the lines in the spectrum of an incandescent gas, taking into account not only the velocities of the molecules, but also the effect of collisions, and of radiative damping in the molecular vibrations. The connection between Röntgen rays and ordinary light is examined, J. J. Thomson's theory of the former being assumed. It is shown that perhaps $\frac{1}{1000}$ of the energy of the rays will be in the visible spectrum. The theory of dispersion is considered with reference to natural light as opposed to a simple harmonic train of waves.

### PARIS.

**Academy of Sciences**, July 10.—M. van Tieghem in the chair.—The Perpetual Secretary announced to the Academy the loss it had sustained by the death of Sir William Flower, Correspondent in the Section of Anatomy and Zoology.—Remarks by M. Ed. Perrier on his *Traité de Zoologie*.—New researches on argon and its combinations, by M. Berthelot. Having a larger quantity of argon placed at his disposal, the author has repeated his earlier observations on the reactions between argon and certain organic compounds. Entirely negative results were obtained when mixtures of argon with ethylene, glycollic ether, aldehyde, acetone, amylene, petroleum ether, propionitrile, allyl sulphocyanide, or amylamine were submitted to the prolonged action of the silent discharge, the original volume of argon being recovered unchanged. With benzene, toluene, cymol, turpentine, anisol, phenol, benzaldehyde, aniline, phenyl sulphocyanide, and benzonitrile, on the other hand, an absorption of argon took place in amounts varying from one to six per cent. At the same time a greenish fluorescence appeared, giving a characteristic spectrum.—On the geographical and cartographical work carried out in Madagascar by order of General Gallieni between 1897 and 1899, by M. Alfred Grandidier. The values previously assumed for the latitude and longitude of Tamatave, Andévorante, Fort Dauphin, and other towns in Madagascar are here revised, and the differences tabulated.—On the dialkylbenzoylbenzoic acids and their tetra-chlor-derivatives, by MM. A. Haller and H. Umbgrove. Details are given of the preparation and properties of tetrachlordimethylamidobenzoylbenzoic acid, acetyldimethylamidobenzoyltetrachlorbenzoic anhydride and the corresponding ethyl and methyl ethers, dimethylamidobenzoyltetrachlorbenzoic acid and the anhydride of acetyldiethylamidobenzoyltetrachlorbenzoic acid, together with its ethyl and methyl ethers.—On the development of analytical functions of several variables, by M. Paul Painlevé.—Contribution to the theory of musical instruments, by M. Firmin Larroque.—Remarks on the use of cryohydrates, by M. A. Ponsot.—Action of nitric oxide upon chromous salts, by M. Chesnau. Chromous salts in solution dissolve nitric oxide like ferrous salts, giving only one compound. On heating, or placing in a vacuum, this compound gives off no gas, thus differing from the corresponding ferrous compound.—On metallic sulphantimonites, by M. Pouget. Solutions of potassium sulphantimonites by double decomposition with salts of metals may give salts of the types $SbS_3M_3$, or $SbS_3M_2K$, but in no case of the type $SbS_3MK_2$.—Action of phenylhydrazine upon alcoholic bromides, chlorides, and iodides, by M. J. Allain Le Canu. The iodides behave differently to the corresponding bromides and chlorides in respect to their reaction with phenylhydrazine.—On the aminocampholenes, by MM. E. E. Blaise and G. Blanc.—Contribution to the study of an oxyptomaine, by M. Œchsner de Coninck. The oxyptomaine $C_8H_{11}NO$ was prepared by the action of hydrogen peroxide upon the pyridic ptomaine, $C_8H_{11}N$. In the present paper details are given of its bromohydrate, chloroaurate, and chloromercurate.—New method for the acidimetric estimation of alkaloids, by M. Élie Falières. The titration is conducted with an ammoniacal copper solution instead of litmus or one of the ordinary indicators. The experimental results were very satisfactory.—On benzoyl-furfurane, by M. R. Marquis. Benzoylfurfurane is readily obtained by the interaction of pyromucyl chloride and benzene in presence of aluminium chloride.—The egols, new general antiseptics, by M. E. Gautrelet. Parasulphones derived from phenols are nitrated, and the ortho-nitro-phenolparasulphonate of mercury and potassium prepared from this. The compounds thus obtained are termed egols, phenegol from phenol, cresegol from cresol, and so on, and possess certain advantages as antiseptic agents.—The *rôle* of heat in muscle action, by M. Raphael Dubois.—New observations on echidnase, by M. C. Phisalix. This ferment is present in snake poison, and is found to exert a diastatic action not only upon animal tissues, but even upon the active principle of snake poison, echidnotoxin.—Analogies between cultures of the vegetable fungus *Nectria* and the parasitic fungus in human cancer, by M. Bra.—On the absence of regeneration of the posterior members of the leaping Orthoptera and its probable causes, by M. Edmond Bordage.—On the affinities of *Microsporum*, by MM. L. Matruchot and Ch. Dassonville.—On the cicatrisation of the fascicular system, and of the secretory apparatus on the falling of the leaf, by M. A. Tison.—Barometric deviations on the meridian of the sun at successive days of the synodic revolution, by M. A. Poincaré.—On the use of self-recording meteorological apparatus in captive balloon ascents, by M. Léon Teisserenc de Bort.

THURSDAY, JULY 27, 1899.

## INORGANIC CHEMISTRY.

*Lehrbuch der Anorganischen Chemie.* Von Prof. Dr. H. Erdmann. Pp. 728. (Brunswick: Vieweg und Sohn, 1898.)

THIS book is based upon the well-known work of Gorup-Besanez, the last edition of which was published in 1878, but it is practically a new book. It is printed in the style of Roscoe and Schorlemmer's treatise, handsomely illustrated, and well bound. In the 728 pages a vast amount of information is given about the facts of inorganic chemistry, and this information is in most respects well abreast of the time. The treatment and presentation of the subject are quite orthodox, except in so far as the description of experiments and of technical applications is separated from the main text, and printed in smaller type after the more general and descriptive account of a substance or group of substances has been written.

It is, perhaps, asking a good deal that a new book on inorganic chemistry should differ much except in size or price from contemporaneous works on the same subject. A perusal of the present work proceeds without any sense of freshness until the sections on helium and argon, where for the first time the personal authority of the writer is felt and approving interest excited. After this the even tenor is resumed until the second part of the work dealing with the metallic elements is reached. Here again interest is aroused, and the author may be congratulated on having produced a very readable account of what, scientifically speaking, is usually the dullest part of a book on inorganic chemistry. The accounts of technical applications which are intercalated in the text are very well written, interesting, and trustworthy.

The chief question raised by this book is how far theory is to be introduced into a book on inorganic chemistry. Is a book on inorganic chemistry to be a compendium of facts, whilst the theory is to be sought in books on general or physical chemistry? As a matter of fact, books on inorganic chemistry written up to about 1870 included a discussion of all that was known of theoretical and physical chemistry. Till then the only important quantitative laws that were clearly established referred to composition, and accordingly the theoretical part of such books dealt mainly with the laws of chemical combination and the atomic and molecular theories. But things have advanced since then; we now know a great deal about chemical dynamics, and it seems anomalous that in such a book as the one under notice there should be no general exposition of the laws governing chemical reactions and chemical equilibrium. These laws, like the laws of composition, are fundamental, and the light they throw on every-day inorganic chemistry is indispensable for a right apprehension of the facts. There seems no good reason for neglecting them in a book of 700 pages dealing with inorganic chemistry.

The theoretical part of the book is also in other respects the least satisfactory feature. It displays much of the anxious striving, to which some minds seem peculiarly liable, to be fundamental and logical on points where such exercitation is quite unnecessary and unfruitful. An advanced student surely does not need to be carefully initiated into the difference between Roman and Arabic numerals, or the meaning of $10^6$, or the impossibility of putting a quart of liquid into a pint pot; yet these and like matters are gravely and lengthily expounded. The effect is to submerge the salient points of doctrine in a sea of tedious disquisition. One cannot but wish that the space so used had been saved for the discussion of such important theoretical matters as the constitution of ozone, the hydration of salts, the absorption of hydrogen by metals, the atomic weight of tellurium—topics to which justice is not done in the book.

There are some omissions and a few mistakes in the book. The account of flame includes the apparently ineradicable dogma that the hydrogen of a hydrocarbon burns preferentially to the carbon, and that solid particles of carbon are burnt up in the mantle. The rate of the explosive wave is confused with the velocity of inflammation, and the acetylene flame, which readily melts a platinum wire, is stated to be peculiarly cool. The blemishes in the book on matters of fact are, however, not many; the information is indeed, on the whole, admirable, and we have no doubt that Prof. Erdmann's work will on this account meet the requirements of a large class of students.

A. S.

## MARINE BOILERS.

*Marine Boilers.* By L. E. Bertin; translated and edited by L. S. Robertson, with a preface by Sir William White, F.R.S. Pp. xxviii + 437. (London: John Murray, 1898.)

THIS is a translation, with some important alterations and additions, of M. Bertin's well-known work on marine boilers. M. Bertin, now Director of Naval Construction for the French Navy, was previously Principal of the *École d'application du Génie Maritime*, and his text-book was the outcome of the course of lectures on boiler construction which he delivered to the students of that institution.

The work has been translated by Mr. L. S. Robertson, an authority on the so-called water-tube boiler, and has the advantage of a graceful tribute to M. Bertin's skill as an engineer and naval architect in the form of a preface by Sir William White, Chief Constructor to the British Navy.

The book is copiously illustrated, but unfortunately the plates are sometimes by no means clear, and where dimensions are given it is often impossible to read them; as the illustrations are reproductions of those in the original French work, the dimensions are in metric units, while all the dimensions in the text have been converted into English units. Fewer illustrations, more clearly reproduced, would have been an improvement; though these remarks apply in the main to the general drawings only, the detail drawings being much clearer.

The author has divided the book into four parts, and has covered fairly completely the whole field. Part i. is devoted to the important subjects of combustion, trans-

mission of heat, corrosion, &c., and to the various methods for producing draught, with a discussion of the advantages and disadvantages of the various systems.

On p. 45 there is a slip, probably arising in conversion of units: it is stated that 5·89 lbs. of oxygen are needed to burn a pound of carbon; the figure should be 2·67 lbs. In discussing the possibility of the utilisation of the heat passing away up the funnel for warming either the feed water or the air before it passes into the furnace, there is a somewhat cur ious remark about the heat wasted in condensing the exhaust steam from an engine by cold water in the condenser, the author stating that so far "no remedy for this evil" had been proposed. Surely it has been forgotten that since the engine can only convert into work a small portion after all of the heat it receives, there must be rejection of heat in the condenser or elsewhere. In discussing the effects of corrosion in tubes, it is laid down as an axiom that only solid drawn tubes should be used, on account of the liability of the welded tube to suffer injury by corrosion along the line of weld, a remark which is sadly significant after the late disaster to a boiler in H.M.S. *Terrible*, and the finding of the Court of Inquiry.

The next two parts deal in detail with the older forms of marine boilers, the Scotch boiler mainly, and the newer tubulous or water-tube boiler. Very full descriptions are given in the second section of the more important details in a cylindrical boiler, especially in regard to the tubes and to the stays, and the section concludes with a valuable table of weights, space occupied, &c.

The third section, on water-tube boilers, is the most complete and the most interesting, as was to be expected, the tubulous boiler now reigning almost supreme in the French navy, and its use in the French mercantile marine being fairly large. Three classes of such boilers are described in three separate chapters—the limited circulation class, type Belleville; the free circulation, types Niclausse, Babcock-Wilcox, &c.; and lastly the accelerated circulation, types Normand, Thornycroft, Yarrow, &c.

In each chapter practically every boiler of the class under description which has been actually tried in practice is illustrated and briefly explained, while very full detailed descriptions are given of one or two of the important forms, such as Belleville, Niclausse, Thornycroft, &c., with much valuable information as to their performances under steam.

The last chapter in Part iii. is devoted to an able summary of the advantages and disadvantages of the tubulous type of boiler, mainly, of course, from the point of view of the marine engineer; interesting contrasting figures of comparative weights, costs, &c., per square foot of grate render this chapter one of the most useful in the book. It is surprising how cheap these apparently complex water-tube boilers are, averaging 32*l*. per square foot of grate surface.

The four chapters in Part iv. are devoted to descriptions of boiler mountings and fittings, in particular to the automatic feed arrangements, so essential to many water-tube boilers; in these chapters the illustrations are very good.

The book undoubtedly is the most complete work on the subject issued in English up to the present, and is well up to date; it should prove a valuable work of reference, not only to the marine engineer, but to the intelligent layman who takes an interest in the efficiency of our navy. The water-tube boiler, much as Mr. Allen may dislike it, has come to stay; in our navy it will gradually displace the old Scotch boiler, and we should be surprised if it does not eventually make headway in the mercantile marine.

Any one reading the book and anxious to ascertain the trend of opinion amongst English marine engineers on this important question should consult the papers read a month or two ago before the Institution of Civil Engineers by Mr. Milton and Sir John Durston.

H. B.

## OUR BOOK SHELF.

*The Elements of Euclid.* With Notes, &c., by I. Todhunter, D.Sc., F.R.S. New edition, revised and enlarged, by S. L. Loney, M.A. Pp. viii + 332, cxxxii. (London: Macmillan and Co., 1899.)

*Essentials of Plane and Solid Geometry.* By W. Wells, S.B. Pp. viii + 392. (London: Isbister and Co. Boston, D.C.: Heath and Co., 1899.)

WITHOUT altering the general character of the well-known text-book with which he has had to deal, Mr. Loney has succeeded very well in bringing it up to date. The appendix has been enlarged by the insertion of sections on poles and polars, harmonic ranges, inversion, coaxal cir cles, &c.; the number of exercises has been doubled, and, what is more important, the really valuable exercises have been starred and hints given for the solution of many of them. To teachers of the conservative school this new edition ought to prove very acceptable.

Mr. Wells' book is of quite another stamp. The author belongs to the progressive party, and makes no scruple of using hypothetical constructions or any abbreviations he finds convenient. In treating of parallels he uses Playfair's axiom, and the discussion of ratio and proportion is distinctly arithmetical. The exercises are numerous and often accompanied by figures; hints for solution are also given in many cases. Mr. Wells writes in a fresh and independent manner, and his book seems very likely to interest a student and develop any geometrical power he may have in the right way.

In another edition the author will, we trust, suppress the appendix (p. 386), which is almost entirely vitiated by an error of reasoning. Mr. Wells proposes, for instance, to prove that the circumference of a circle is less than the perimeter of any circumscribed polygon, and proceeds thus: "Of the perimeters of the circle and of its circumscribed polygons, there must be one perimeter such that all the others are of equal or greater length." He then proves that, given any circumscribed polygon, we can construct another one with less perimeter; and then infers the truth of the proposition. As a matter of fact, the statement quoted above is not justifiable; the perimeters of the polygons form a manifold, and this does not necessarily contain a least element; indeed, Mr. Wells shows that it does not. There may be a definite lower limit to the perimeter of a circumscribed polygon: even then, Mr. Wells brings forward no argument to show that this lower limit exists; still less that it is equal to the circumference of the circle. Strictly speaking, he brings the circumference of the circle into no relation of equality or inequality with any of the polygons: it just stands by itself at the end as at the beginning. It is as if one said: "We have a set of quantities $x$, 1·3, 1·33, 1·333, &c.; one of these must be at least equal to any of the rest. But this cannot be any of the decimals, because if we choose,

say, 1·3333, we can write down 1·33333, which is greater. *Therefore it must be x!*"

It is only fair to add that this unlucky paralogism seems to be a solitary blemish in an otherwise excellent book. G. B. M.

*A Manual of Surgical Treatment.* By W. Watson Cheyne, F.R.S., and F. F. Burghard, M.S., Surgeons to King's College Hospital, London. In six Parts. Part I. Pp. xiv + 285, with 66 illustrations in the text. (London and Bombay: Longmans, Green, and Co., 1899.)

SUCH a work as this has long been wanted by senior students, house-surgeons and general practitioners, who are often left in charge of capital operations performed by surgeons of repute without any precise directions as to the treatment to be adopted in cases of emergency. But the work undertakes much more than this, for it is evident that the authors will review the whole field of surgery in the light of our present pathological knowledge, showing the modern methods of treatment and explaining why they have replaced the older plans. The present part deals with the more general subjects of inflammation, gangrene, wounds, venereal disease, tuberculosis and tumours. It treats, therefore, of those parts of surgery which, perhaps more than all others, have been affected by antiseptic treatment. Mr. Watson Cheyne is so well known as one of the most distinguished pupils of Lord Lister that no better exponent of his methods could be found, and we are here presented with a clear account of the rationale of modern treatment. Thus, amongst many other more important things, we learn why poulticing is bad in the treatment of abscess, why a chronic abscess should be scraped, but an acute abscess should only have the matter let out and the loculi broken down. The facts and reasoning are excellent, but the pleasure of reading is too often marred by the form in which they are presented, as many of the sentences seem to be constructed upon a German model. The figures which illustrate the letterpress vary greatly in quality; some are excellent, others are sketchy, whilst others again are such mere outlines as to be almost unintelligible. Dr. Silk contributes an excellent article on the subject of anæsthetics, and there is a good index to this first part of the work.

*Impressions of America.* By T. C. Porter, M.A. (Oxon.), Fellow of the Chemical Society, of the Royal Astronomical Society, and of the Physical Society of London. Illustrated with diagrams and stereoscopic views. Pp. xviii + 242. (London: C. Arthur Pearson, Ltd., 1899.)

THE impressions were obtained during a pleasure trip to Niagara, the Yellowstone Park, San Francisco, the Yosemite, Utah and Colorado Springs. The author refrains from citing any of the scientific works dealing with the remarkable features of those interesting regions, but gives a graphic account of what he himself saw, and outlines a number of interesting hypotheses to account for some of the phenomena. Some of these are interesting because they show how a man of scientific habits of thought may from a hasty glance often reach conclusions very similar to those which the specialists who have studied the subject for years have demonstrated to be correct. We cannot accept Mr. Porter's ingenious hypothesis that the spiral ridges of the trunks of many trees in the Yellowstone Park are due to unequal heating by the sun and the uniform rotation of the earth, because he does not buttress it with the necessary explanation why trees in other places in the same latitude where the sun also shines unequally and the earth rotates uniformly do not also incline to a screwy form. But the little appendix on the Gulf Stream is a neat demonstration from the study of a single bottle-chart of the seasonal variation of the Gulf Stream and its attendant drift. Of course the deduction is not new; the fine charts of North Atlantic currents grouped for two-monthly intervals by the Meteorological Office bring it out perfectly, and the labours of American, British, and Scandinavian oceanographers, and of the Prince of Monaco, have done much to find the reasons for the observed variations. We might venture, however, to remind Mr. Porter that the course of the Gulf Stream shown on a single small scale map is as conventional and empirical a representation of oceanic circulation as the isotherms on a map of mean annual temperature are of the climates of the world. The generalisation in no way implies that the seasonal changes are unknown.

A new theory of geysers to fit the phenomena of the Yellowstone Park is also printed in the appendix in the form of a paper read to the Physical Society. It points out defects in Tyndall's well-known theory, and introduces a syphon-bend in the underground channel and the spheroidal state induced by the intense heat of the rocks as more probable explanations.

The great merit and the unique character of the book depend, however, not on the author's impressions or his theories, but on the incomparable series of photographs which he took. These are reproduced in the form of stereoscopic views, and a neat little lenticular stereoscope is supplied with the volume. The views shown in these illustrations are admirably selected and splendidly photographed. They are reproduced by the half-tone process as separate plates, and very well printed. As a diary of the observations of a man of science at leisure there is much of interest in the whole book, which has also the advantage of being brief. H. R. M.

*Tables for Quantitative Metallurgical Analysis for Laboratory Use.* By J. James Morgan, F.C.S., Member Soc. Chem. Industry, Member Cleveland Inst. Engineers. Tables xvi. (London: Charles Griffin and Co., Ltd., 1899.)

TABLES for qualitative analysis are to be found in every chemical laboratory, and are used by every analyst at one time or another. Any attempt to supply chemists with information on quantitative analysis drawn up in the same convenient form must therefore be welcome. The present collection of tables has been carefully prepared, and is well arranged. It includes the analyses of iron ores, steel, limestone, boiler incrustation, certain slags, gaseous fuels, water, coal, and a few of the common metals and alloys. Alternative methods are not given, but the tables will be found very useful in saving the time of an analyst engaged in the examination of materials with which he is not accustomed to deal in the ordinary course of his daily work.

## LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

### Tides of the Gulf and River St. Lawrence and Bay of Fundy.

PERMIT me to invite your attention to the latest report of the engineer in charge of the survey of the tides and currents of the coast waters of Canada, Mr. W. Bell Dawson, a copy of which has been addressed to you.

This survey, commenced by the Government of Canada in 1894, is of great importance, not merely in the interest of hydrographical science, but of the large and increasing trade which finds its way along the gulf and river St. Lawrence, the greatest water-way from the North Atlantic into the northern part of the American continent, and which, like all

similar tide-ways, is affected by the complex action of the tides and consequent currents.

It is much to be regretted that the economy or parsimony of the Government has caused a suspension for the present of the special survey of the currents, and has restricted the work to tidal observations, which, though of great value to the shipping interests, can only be considered as preliminary in regard to the investigation of the currents themselves, which lead to so many losses of property and life, and tend to high rates of insurance, injurious to the shipowners and merchants of Canada, and through them to those of an empire as a whole.

The present report, in addition to what can be done with the insufficient grant allowed, in the matter of tide-gauges and tide-tables, has reference to the behaviour of the gigantic tides of the Bay of Fundy, when confined by the converging coasts at the head of the bay, and their relation to the smaller tides on the opposite side of the isthmus connecting Nova Scotia and New Brunswick at Bay Verte on the Gulf of St. Lawrence. These and the phenomena of the "bore" at the head of the Bay of Fundy are here for the first time described, illustrated by maps and sections, and tabulated, and will be found of the greatest interest by all who desire information as to the exceptional tides of this region.

J. W. DAWSON.

### School Laboratory Plans.

As one who has had the privilege of seeing Mr. Dymond's excellent arrangement and outlay of money in his laboratory at Chelmsford, may I make a comment on his letter in your issue of July 13? I think the conditions of work in an average school laboratory show some points of difference from those in Mr. Dymond's laboratory. Of course qualitative analysis is now confined to quite senior boys, who can be persuaded not to treat the subject as if they were working from a cookery book; but though owning no allegiance to the Science and Art Department, I believe that drawers and lockers are valuable, not only in relieving the general stock of the laboratory (very heavy for descriptive and quantitative work) of some smaller apparatus in constant use, but also in conferring a feeling of ownership, which induces some care and respect in a boy for his belongings. With snap-locks answering to one master key, and the lockers of each class bearing a label of a distinctive colour, they may be at once opened by the assistant before a class, so that there need be no keys to lose and no depredations on neighbouring lockers. Mr. Dymond's objection to that most durable of woods—teak—or why it alone should be left in a dirty state, I do not understand. Admitting that in all but very elementary work some tuition in the way of lectures is necessary, a laboratory will generally possess a lecture room; and where this is a separate room, I grudge the space usually given to a demonstrator's table in the laboratory, because no large section of a practical class is ever doing the same experiment at the same time. Physics, again, is often involved in this question of arrangement in a school, since the two subjects may, I think, with little detriment and great economy often have a common lecture room. Considering the prodigal waste of space often seen in laboratories, and the number now being built by public bodies, some further views on this subject ought to be of value.

A. E. MUNBY.

Felsted School.

### Duties of Provincial Professors.

THE article in your issue of July 13 upon "The Duties of Provincial Professors" will be welcomed by all professors in local university colleges. It insists none too strongly upon the disadvantageous position they occupy with regard to the opportunity for the prosecution of original research, and the unfortunate result of compelling our best students to complete their scientific education in Germany.

It is not sufficiently recognised that the reputation of a university is advanced more by the contributions to science and literature produced by its staff than by the mere number of its students. Unfortunately, the staff of assistants in the university colleges is often totally inadequate to the work required, and the knowledge that their energies will be dissipated in elementary teaching, and no time given for continuing original investigation, is deterring men of really high academic distinction from accepting such appointments. The government of a local college is largely directed by business men, and the methods which ensure commercial success are hardly those best calculated to further the interests of true education. Salvation lies apparently in the fact of Government inspection; the Government grant is only given when the education is of an advanced university type; and, judging from the tenor of the Treasury Minute, "University Colleges, Great Britain—Grant in Aid," the fullest recognition is given to those colleges which offer opportunities for advanced work and research and can show an adequate educational equipment.

"A PROFESSOR."

July 23.

IN the articles on "The Duties of Provincial Professors," it is stated: "In such cases students . . . may be called on to give evidence against their professors." This is almost incredible, but, to my great astonishment, I learnt quite lately that the only possible alteration in the statement consistent with truth would be the substitution of the words "have been" for "may be." The adoption of such a course must be fatal to good discipline in a college, and it leaves the members of the staff at the mercy of a few unruly and ignorant students whose disposition to learn may be small, though their capacity for agitation is great. From time to time students of this description will be found in every college. Apart altogether from these evils, there is another reason why the practice of allowing students to give evidence against a professor is decidedly objectionable; and that is, the lay members of the governing body of a provincial college are not likely to fully understand how incompetent the average pass student is to form an opinion as to the soundness of the teaching he receives.

In the interests, not merely of the provincial colleges, but of higher education throughout the country, it is desirable that professors should not, for any except very grave reasons, and then only after a perfectly fair trial, be forced to resign their offices.

P.

## *THE REDE LECTURE.*[1]

### THE WAVE THEORY OF LIGHT: ITS INFLUENCE ON MODERN PHYSICS.

OUR era is distinguished from preceding ages by wonderful utilisation of natural forces; man, that weak and defenceless being, has been enabled by his genius to acquire an extraordinary power, and to bend to his use those subtle yet dreadful agents whose very existence was unknown to our ancestors. This marvellous increase of his material power in modern times is due only to the patient and profound study of natural phenomena, to the exact knowledge of the laws that governed them, and to the skilful combining of their effects. But what is peculiarly instructive is the disproportion between the primitive phenomenon and the greatness of the effects which industry has drawn from it. Thus, those formidable engines, based on electricity or steam, grew neither from lightning nor the volcano; they had their birth from scarcely perceptible phenomena which would have remained for ever hidden from the vulgar eye, but that penetrating observers were able to recognise and appreciate. This humble origin of most of the great discoveries which are to-day a benefit to the

[1] Besides the interest presented by a glance on the progress and the influence of optical science, this lecture offers the conclusions of a careful study on Newton's treatise of optics. It will be seen that the thought of the great physicist has been singularly altered by a sort of legendary interpretation developed in the elementary treatises where the emission-theory is expounded. In order to make the theory of fits clearer, the commentators have imagined to materialise the luminous molecule under the form of a rotating arrow offering now its head, now its side. This mode of exposition has contributed to lead to the belief that the whole emission-theory was comprehended in this rather childish image.

Nowhere in his treatise does Newton give a mechanical illustration of the luminous molecule: he confines himself to the description of facts, and sums them up in an empirical statement without any hypothetical explanation. Moreover, he denies the opinion that he raises any theory, though he holds occasionally as very probable the intervention of the waves excited in the ether.

So that the general impression resulting from the reading of the treatise and above all of the "queries" in the 3rd Book, is the following: Newton, far from being the adversary of the Cartesian system, as he is commonly represented, looks, on the contrary, very favourably at the principles of this system. Struck by the resources which the undulatory hypothesis would offer for the explanation of the luminous phenomena, he would have adopted it, if the grave objection concerning the rectilinear propagation of light (only recently solved by Fresnel) had not prevented him.

whole human race, shows us plainly that the scientific spirit is at present the mainspring of the life of nations, and that it is in the onward march of pure science that we are to look for the secret of the growing power of the modern world. Whence a series of questions which demand more and more the attentions of all. How did this taste towards the study of natural philosophy, so dear to the ancient philosophers, abandoned for centuries, again revive and grow? What are the phases of its advance? How appeared the new notions which have so deeply modified our ideas on the mechanism of nature's forces? What paths, rich in discoveries, lead us gradually unawares to those admirable generalisations in accordance with the vast plan foreseen by the founders of modern physics? These are the questions which as a physicist I intend to inquire into before you. The subject is rather abstract, I might say severe. But no other has seemed more worthy of your attention during the *fête* which the University of Cambridge celebrates to-day in honour of the Lucasian Professorship Jubilee of Sir Geo. Gabriel Stokes, who in his fine career has laid a master-hand on the very problems which seemed to me the most conducive to the progress of natural philosophy. The subject is all the more fitted here, as in citing the names of those great minds to whom modern science is most indebted, we found amongst those who most honoured the University of Cambridge—its Professors and Fellows—Sir Isaac Newton, Thomas Young, George Green, Sir George Airy, Lord Kelvin, Clerk Maxwell, Lord Rayleigh, and the memory of that glory which links to-day back through the centuries would add lustre to the present ceremony.

Let us then, in a rapid glance of the scientific revival, point out the secret but mighty influence which has been the directing force of modern physics. I am inclined to attribute to the study of light, and to the attraction it has for the highest minds, one of the most effective causes of the return of ideas towards natural philosophy, and consider optics as having exercised on the advance of science an influence it would be difficult to exaggerate. This influence, already clear at the dawn of the experimental philosophy under Galileo, grew so rapidly that to-day it is easy to foresee a vast synthesis of natural forces founded on the principles of the wave theory of light. This influence is easy to understand if we reflect that light is the way by which knowledge of the exterior world reaches our intelligence. It is, in fact, to sight that we owe the quickest and most perfect notions of the objects around us: our other senses, hearing, feeling, also bring their share of learning, but sight alone affords us abundant means of simultaneous information such as no other sense can. It is, therefore, not surprising that light, this lasting link between us and the outward world, should intervene with the varied sources of its inner constitution to render more precise the observation of natural phenomena. Thus each discovery concerning new properties of light has had an immediate effect on the other branches of human knowledge, and has indeed determined the birth of new sciences by affording new means of investigation of unexpected power and delicacy.

Optics are really a modern science. The ancient philosophers had no idea of the complexity of what is vulgarly called light; they confounded in the same name what is proper to man, and what is exterior. They had, however, perceived one of the characteristic properties of the link, which exists between the source of light and the eye, which receives the impression, "Light moves in a straight line." Common experience had revealed this axiom through the observation of the shining trains that the sun throws across the skies, piercing misty clouds, or penetrating into some dark space. Hence arises two empirical notions—the definition of the ray of light, and that of the straight line. The one became the basis of optics, the other that of geometry.

Very little remains to us of the ancient books upon optics. Yet we are aware that they knew the reflection of the luminous rays on polished surfaces, and the geometrical explanation of the images formed by mirrors.

We must wait many centuries until the scientific revival for a new progress in optics (but then a very considerable one) opens the new era; it is the invention of the telescope.

The new era begins with Galileo, Boyle and Descartes, the founders of experimental philosophy. All devote their life to meditations on light, colours, and forces. Galileo lays the base of mechanics and with the refracting telescope that of astro-physics. Boyle improves experimentation. As to Descartes, he embraces with his penetrating mind the whole of natural philosophy; he throws away the occult causes admitted by the scholastics, and proclaims as a principle that all phenomena are governed by the laws of mechanics. In his system of the universe, light plays a prominent part [1]: it is produced by the waves excited in the subtle matter which, according to his view, pervades space. This subtle matter (which represents what we call to-day the ether) is considered by him as formed of particles in immediate contact; it constitutes thus at the same time the vehicle of the forces existing between the material bodies which are plunged in it. We recognise the famous "vortices of Descartes," sometimes admired, sometimes baffled during the last centuries, but to which skilful contemporaneous physicists have rendered the importance they deserve.

Whatever may be the opinions granted to the exactness of the deductions of this great philosopher, we must be struck by the boldness with which he proclaims the connection of the great cosmical problems, and foretells the solutions which actual generations did not yet entirely accept but drew insensibly to.

In Descartes' view the mechanism of light and that of gravitation are inseparable; the seat of corresponding phenomena is this subtle matter which pervades the universe, and their propagation is performed by waves around the acting centres.

This conception of the nature of light shocked the opinions in vogue; it raised strong opposition. Since the oldest times it was the habit to imagine the luminous ray as the trajectory of rapid projectiles thrown by the radiant source. Their shock on the nerves of the eye produce vision; their resistance or changes of speed, reflection or refraction. The Cartesian theory had, however, some seductive aspects which brought defenders. The waves excited on the surface of still water offer so clear an image of a propagated motion around a disturbing centre! On the other hand, do not the sonorous impressions reach our ear by waves? Our mind feels yet a real satisfaction in thinking that our most sharp and delicate organs are both impressed by a mechanism of the same nature.

Yet a serious difference arose. Sound does not necessarily travel in straight lines as light does. It travels round any object opposed to it, and will follow the most circuitous routes with scarcely any loss of strength. Physicists were thus divided into two camps. In one the partisans of emission, in the other those of the wave theory, each system boasting itself superior, and indeed each being so in certain respects. Other phenomena had to be examined in order to decide between them.

The chance of discovery brought to view several phenomena which ought to have decided in favour of wave theory, as was proved a century later; but the simplest truth does not prevail without long endeavour.

A strange compromise was effected between the two systems, helped on by a name great among the greatest, and for a century the theory of emission triumphed.

The tale is a strange one. In 1661 a young scholar,

[1] *Le Monde de M. Descartes, ou le Traité de la Lumière* (Paris, 1664).

full of eagerness and penetration, enters Trinity College, Cambridge; his name is Isaac Newton. He has already in his village read Kepler's "Optics." Almost immediately, and while following Barrow's lectures upon optics, he studies the geometry of Descartes with passionate care; with his savings he buys a prism that he might examine the properties of colour and meditate deeply on the causes of gravitation. Eight years later his masters think him worthy to succeed Barrow in the Lucasian Professorship, and in his turn he also teaches optics. The pupil soon becomes greater than his teacher, and he gives out this great result: White light which seemed the type of pure light is not homogeneous; it consists of rays of different refrangibility, and he demonstrates it by the celebrated experiment of the solar spectrum, in which a ray of white light is decomposed into a series of coloured rays like a rainbow; each shade of the colour is simple, for the prism does not decompose the shade. This is the origin of the spectral analysis. This analysis of white light brought Newton to explain the colours of the thin plates which are, for instance, observed in soap-bubbles. The fundamental experiment, that of Newton's rings, is one of the most instructive in optics, while the laws that govern it are of admirable simplicity.

The theory was expounded in a discourse addressed to the Royal Society with the title, "A New Hypothesis concerning Light and Colour."

This discourse called forth from Hooke a sharp complaint. Hooke also had already examined the colour of thin plates, and endeavoured to explain them in the wave system. He had the merit, which Newton himself readily granted, to substitute for the progressive wave of Descartes a vibrating one—a new and extremely important notion. He had even noticed the part of the two reflecting surfaces of the thin plate, and the mutual action of the reflected waves. Consequently Hooke should have been the very forerunner of the modern theory if he had had, as Newton, the clear intelligence of the simple rays. But his vague reasoning to explain the colours takes away all demonstrative value from his theory.

Newton is very affected by this complaint of priority, and combats the arguments of his adversary by remarking that the wave theory is inadmissible because it does not explain the existence of the luminous ray and of the shadows. He denies the opinion that he has raised a theory; he certifies that he does not admit either the wave hypothesis or the emission, but he says "He shall sometimes, to avoid circumlocution and to represent it conveniently, speak of it as if he assumed it and propounded it to be believed." And, really, in the Proposition XII. (second book of his Optics),[1] which constitutes what was since called the theory of fits, Newton remains absolutely on the ground of facts. He says simply, the phenomena of thin plates prove that the luminous ray is put alternatively in a certain state or fit of easy reflexion and of easy transmission. He adds, however, that if an explanation of these alternative states is required they can be attributed to the vibrations excited by the shock of the corpuscles, and propagated under the form of a wave in ether.[2]

After all, notwithstanding his desire to remain on the firm ground of facts, Newton cannot help trying a rational explanation. He has too carefully read the writings of Descartes not to be heartily, as Huygens, a partisan of the universal mechanism and not to wish secretly to find in the pure undulations the explanation of the beautiful phenomena he has reduced to such simple laws. But his third book on optics more especially proves his Cartesian aspirations, and, above all, his perplexity. His famous "Queries" expose so forcibly his argument in favour of the wave theory of light that Thos. Young will later cite them as proof of the final conversion of Newton to the wave theory. Newton would certainly have yielded to this secret inclination had the inflexible logic of his mind allowed him to do so; but when after enumerating the arguments the wave theory of light offers in explanation of the intimate nature of light, when he arrived at the last "queries" he stops, as if seized by a sudden remorse, and throws it away. And the sole argument is that he does not see the possibility of explaining the rectilinear transmission of light.[1] Viewed from this standpoint the third book of *Optiks* is no longer only an

[1] Prop. XII.—Every Ray of Light in its passage through any refracting Surface is put into a certain transient constitution or state, which in the progress of the Ray returns at equal Intervals, and disposes the Ray at every return to be easily transmitted through the next refracting Surface, and between the returns to be easily reflected by it. (Sir Isaac Newton, "*Opticks*: or a *Treatise* of the Reflections, Refractions, Inflexions and Colours of *Light*." London, 1718. Second edition, with additions. P. 293.

[2] *Loc. cit.*, p. 299.

[1] First, here is an extract from the "Queries" which prove the leaning of Newton's views towards the undulatory theory and the Cartesian ideas.

"Query 12.—Do not the Rays of light in falling upon the bottom of the eye excite Vibrations in the *Tunica Retina*? Which Vibrations, being propagated along the Solid Fibres of the optick nerves into the brain, cause the Sense of seeing. . ."

"Query 13.—Do not several sorts of Rays make Vibrations of several bignesses, which, according to their bignesses, excite sensations of several colours, much after the manner that the vibrations of the air, according to their several bignesses, excite sensation of several sounds? And particularly do not the most refrangible rays excite the shortest vibrations for making a sensation of deep violet, the least refrangible the largest for making a sensation of deep red, &c.? . . ."

"Query 18.— . . . Is not the heat of the warm room convey'd through *the vacuum* by the vibrations of a much subtiler medium than air, which, after the air was drawn out remained in the *vacuum*? [ether] and is not this medium the same with that medium by which light is refracted and reflected, and by whose vibrations light communicates heat to bodies, and is put into fits of easy reflection and easy transmission? . . . And is not this medium exceedingly more rare and subtile than the air, and exceedingly more elastic and active? and doth it not readily pervade all bodies? and is it not (by its elastick force) expanded through all the heavens?"

Newton, afterwards, considers the possible connection of this medium (ether) with the gravitation and the transmission of the sensations and motion in living creatures (queries 19 to 24).

The dissymetrical properties of the two rays propagated in the Iceland spar, draw equally his attention (query 25 to 26).

Here appears this sudden and unexpected going back, this sort of remorse from having too kindly expounded the resources of the Cartesian theory, based on the *plenum*; he makes an apology as follows:

"Query 27.—Are not all hypotheses erroneous which have hitherto been invented for explaining the phenomena of light, by new modifications of the rays? . . ."

"Query 28.—Are not all hypotheses erroneous in which light is supposed to consist in pression or motion, propagated through a fluid medium? . . . and if it (light) consisted in pression or motion, propagated either in an instant or in time, it would bend into shadow. For pression or motion cannot be propagated in a fluid in right lines beyond an obstacle, which stops part of the motion, but will bend and spread every way into the quiescent medium which lies beyond the obstacle. . . . For a bell or a canon may be heard beyond a hill which intercept the light of sounding body, and sounds are propagated as readily through crooked pipes as through straight ones. But light is never known to follow crooked passages nor to bend into the shadow. . . ."

Stopping before this objection Newton is forced to come back to the corpuscular theory.

"Query 29.—Are not the rays of light very small bodies emitted from shining substances? . . ."

"Query 30.—Are not gross bodies and light convertible into one another . . . ? The changing of bodies into light and light into bodies, is very conformable to the course of nature, which seems delighted with transmutations. . . ."

Logic urges him to go on with the old hypothesis of the *vacuum* and *atoms*, and even to invoke the authority of the Greek and Phœnician philosophers in this matter (query 28, p. 343), therefore it is not surprising to see his perplexity expressed by the following words:—

"Query 31, and the last.—Have not the small particles of bodies certain powers, virtues, or forces, by which they act at a distance not only upon the rays of light for reflecting, refracting and inflecting them, but also upon one another for producing a great part of the phenomena of nature? . . ."

But he perceives that he is going rather far, and compromising himself, therefore his secret tendency, developed in the foremost queries, reappear a little while:—

". . . How these attractions may be performed I do not here consider. What I call attraction may be perform'd by impulse, or by some other means unknown to me . . ."

Many other curious remarks could be made on the state of mind of the great physicist, geometer and philosopher, which is artlessly revealed in those "queries." The preceding short extracts are sufficient, I believe, to justify the conclusion which I get from the study of the 3rd Book, namely, that Newton had not at all on the mechanism of light the definite ideas which have been attributed to him as founder of the emission-theory. Really, he is hesitating between the two opposite systems, perceiving clearly their insufficiency; and in this discussion he is endeavouring to go away as little as possible from the facts. That is the reason for which he has stated no dogmatic theory. It would be, therefore, unjust to make Newton responsible for every consequence which the emission partisans have sheltered under his authority.

impartial discussion of opposite systems; it appears as the painting of the suffering of a mighty genius, worried by doubt, now led away by the seductive suggestions of his imagination, now recalled by the imperious requirements of logic. It is a drama: the everlasting struggle between love and duty; and duty won.

Such, I take it, is the inner genesis of the theory of fits—a strange mingling of two opposite systems. It was much admired, presented, as it was, by the great mathematician, who had the glory of submitting the motions of all celestial bodies to the one law of universal gravitation.

To-day this theory is abandoned; it is condemned by the *experimentum crucis* of Arago, realised by Fizeau and Foucault. One ought, however, to acknowledge that it has constituted a real progress by the precise and new notions which it contains. The ray of light, considered up till then, was simply the trajectory of a particle in rectilinear motion; the ray of light, such as Newton described it, possesses a regular periodic structure, and the period or interval of fits, characterises the colour of the ray. This is an important result. It only requires a more suitable interpretation to transform the luminous ray into a vibratory wave; but we had to wait a century, and Dr. Thomas Young, in 1801, had the honour of discovering it.

Resuming the study of thin plates, Thomas Young shows that everything is explained with extreme simplicity, if it be supposed that the homogeneous luminous ray is analogous to the sonorous wave produced by a musical sound; that the vibrations of ether ought to compose—that is to say, to interfere—according to the expression that he proposes as to their mutual actions.

Although Young had taken the clever precaution of supporting his views by the authority of Newton,[1] the hypothesis found no favour; his principle of interference led to this singular result that light added to light could, in certain cases, produce darkness, a paradoxical result contradicted by daily experience. The only verification that Young brought forward was the existence of dark rings in Newton's experiment, darkness due, according to him, to the interference of waves reflected on the two faces of the plate. But as the Newtonian theory interpreted the fact in a different manner, the proof remained doubtful; an *experimentum crucis* was wanting. Young did not have the good success to obtain it.

The theory of waves relapsed then once more into the obscurity of controversy, and the terrible argument of the rectilinear propagation was raised afresh against it. The most skilled geometers of the period—Laplace, Biot, Poisson—naturally leaned to the Newtonian opinion; Laplace in particular, the celebrated author of the "Mecanique Celeste," had even taken the offensive. He was going to attack the theory of waves in its most strongly fortified entrenchments, which had been raised by the illustrious Huygens.

Huygens, indeed, in his "Traité de la Lumière," had resolved a problem before which the theory of emission had remained mute; that is to say, the explanation of the double refraction of Iceland spar: the wave theory (on the contrary) reduced to the simplest geometrical construction the path of the two rays, ordinary and extraordinary; experiment confirmed the results in every point. Laplace succeeded in his turn (with the help of hypotheses of the constitution of luminous particles) to explain the path of these strange rays. The victory of the theory of particles then appeared complete; a new phenomenon arrived also appropriately to render it striking.

Malus discovered that a common ray of light reflected under a certain angle acquired unsymmetrical properties similar to those rays from a crystal of Iceland spar. He explained this phenomenon by an orientation of the luminous molecule, and, consequently, named this light *polarised light*. This was a new success for emission.

The triumph was not of long duration. In 1816 a young engineer, scarcely out of the École Polytechnique, Augustin Fresnel, confided to Arago his doubts on the theory then in favour, and pointed out to him the experiments which tended to overthrow it.

Supporting himself on the ideas of Huygens, he attacked the formidable question of rays and shadows, and had resolved it: all the phenomena of diffraction were reduced to an analytical problem, and observations verified calculation marvellously. He had, without knowing it, rediscovered Young's reasonings as well as the principle of interference; but more fortunate than he, he brought the *experimentum crucis*—the two-mirror experiment; there, two rays, issuing from the same source, free from any disturbance, produced when they met, sometimes light, sometimes darkness. The illustrious Young was the first to applaud the success of his young rival, and showed him a kindness which never changed.

Thus, thanks to the use of two-mirror experiment, the theory of Dr. Young (that is to say, the complete analogy of the luminous ray and the sound wave) is firmly established.

Moreover, Fresnel's theory of diffraction shows the cause of their dissimilarity; light is propagated in straight lines because the luminous waves are extremely small. On the contrary, sound is diffused because the lengths of the sonorous waves are relatively very great.

Thus vanished the terrible objection which had so much tormented the mind of great Newton.

But there remained still to explain another essential difference between the luminous wave and the sonorous wave; the latter undergoes no polarisation. Why is the luminous wave polarised?

The answer to this question appeared so difficult that Young declared he would renounce seeking it. Fresnel worked more than five years to discover it; the answer is as simple as unexpected. The sound wave cannot be polarised because the vibrations are longitudinal; light, on the other hand, can be polarised because the vibrations are transverse, that is to say, perpendicular to the luminous ray.

Henceforth the nature of light is completely established, all the phenomena presented as objections to the undulatory theory are explained with marvellous facility, even down to the smallest details.

I would fain have traced by what an admirable suite of experiment and reasoning Fresnel arrived at this discovery, one of the most important of modern science: but time presses.

It has sufficed me to explain how very great the difficulties were which he had to overcome in order to establish it.

I hasten to point out its consequences.

You saw, at starting, the purely physiological reasons which make the study of light the necessary centre of information gathered by human intelligence. You judge now, by the march of this long development of optical theories, what preoccupations it has always caused to powerful minds interested in natural forces. Indeed, all the phenomena which pass before our eyes involve a transmission to a distance of force or movement; let the distance be infinitely great, as in celestial space, or infinitely small, as in molecular intervals, the mystery is the same. But light is the agent which brings us the movement of luminous bodies; to fathom the mechanism of this transmission is to fathom that of all others, and Descartes had the admirable intuition of this when he comprehended all these problems in a single mechanical conception: here is the secret bond which has always attracted the physicists and geometers towards the study

[1] The Bakerian Lecture, "On the Theory of Light and Colours." By Thomas Young. *Phil. Trans.* of the R.S. for the year 1802.

of light. Looked at from this point of view, the history of optics acquires a considerable philosophical importance; it becomes the history of the successive progress of our knowledge on the means that nature employs to transmit movement and force to a distance.

The first idea which came to the mind of man (in the savage state) to exercise his force beyond his reach is the throwing of a stone, of an arrow or of some projectile; this is the germ of the theory of emission. This theory corresponds to a philosophical system which assumes an empty space in which the projectile moves freely. At a more advanced degree of culture, man having become a physicist, has had the more delicate idea of the transmission of movement by waves, suggested at first by the study of waves, afterwards by that of sound.

This second way supposes, on the other hand, that space is a plenum; there is no longer here transport of matter; particles oscillate in the direction of propagation, and it is by compression or rarefaction of a continuous elastic medium that movement and force are transmitted. Such has been the origin of the theory of luminous waves; under this form it could only represent a part of the phenomena; it was therefore insufficient.

But geometers and physicists before Fresnel did not know of any other undulatory mechanism in a continuous medium.

The great discovery of Fresnel has been to reveal a third mode of transmission quite as natural as the preceding one, but which offers an incomparable richness of resources. These are the waves of transverse vibrations excited in an incompressible continuous medium, those which explain all the properties of light.

In this undulatory mode the displacement of particles brings into play an elasticity of a special kind; this is the relative slipping of strata concentric to the disturbance which transmits the movement and the effort. The character of these waves is to impose on the medium no variation of density as in the system of Descartes. The richness of resource mentioned above depends upon the fact that the form of the transverse vibration remains indeterminate, and thus confers on waves an infinite variety of different properties.

The rectilinear, circular and elliptical forms characterise precisely the polarisations, so unexpected, which Fresnel discovered, and by the aid of which he has so admirably explained the beautiful phenomena of Arago produced by crystallised plates.

The possible existence of waves which are propagated without change of density, has profoundly modified the mathematical theory of elasticity. Geometers found again in their equations, waves having transverse vibrations which were unknown to them; they learnt besides, from Fresnel, the most general constitution of elastic media, of which they had not dreamt.

It is in his admirable memoir on double refraction that this great physicist set forth the idea that in crystals the elasticity of the ether ought to vary with the direction, an unexpected condition and one of extreme importance, which has transformed the fundamental bases of molecular mechanics; the works of Cauchy and Green are the striking proofs of it. From this principle Fresnel concluded the most general form of the surface of the luminous wave in crystals, and found (as a particular case) the sphere and ellipsoid that Huygens had assigned to the Iceland spar crystal. This new discovery excited universal admiration among physicists and geometers; when Arago came to expound it before the Académie des Sciences, Laplace, who had been such a long time hostile, declared himself convinced. Two years later Fresnel, unanimously elected a member of the Academy, was elected with the same unanimity foreign member of the Royal Society of London; Young himself transmitted to him the announcement of this distinction, with personal testimony of his sincere admiration.

The definite foundation of the undulatory theory imposes the necessity of admitting the existence of an elastic medium to transmit the luminous movement. But does not all transmission to a distance of movement or of force imply the same condition? To Faraday is due the honour of having, like a true disciple of Descartes and Leibnitz, proclaimed this principle, and of having resolutely attributed to reactions of surrounding media the apparent action at a distance of electrical and magnetic systems. Faraday was recompensed for his boldness by the discovery of induction.

And since induction acts even across a space void of ponderable matter, one is forced to admit that the active medium is precisely that which transmits the luminous waves, the ether.

The transmission of a movement by an elastic medium cannot be instantaneous; if it is truly luminous ether that is the transmitting medium, ought not the induction to be propagated with the velocity of luminous waves?

The verification was difficult. Von Helmholtz, who tried the direct measurement of this velocity, found, as Galileo formerly, for the velocity of light a value practically infinite.

But the attention of physicists was attracted by a singular numerical coincidence. The relation between the unity of electrostatic quantity to the electro-magnetic unit is represented by a number precisely equal to the velocity of light.

The illustrious Clerk Maxwell, following the ideas of Faraday, did not hesitate to see in the relationship the indirect measure of the velocity of induction, and by a series of remarkable deductions he built up this celebrated electro-magnetic theory of light, which identifies in one mechanism three groups of phenomena completely distinct in appearance, light, electricity, and magnetism.

But the abstract theories of natural phenomena are nothing without the control of experiment.

The theory of Maxwell was submitted to proof, and the success surpassed all expectation. The results are too recent and too well known, especially here, for it to be necessary to insist upon them.

A young German physicist, Henry Herz, prematurely lost to science, starting from the beautiful analysis of oscillatory discharges of Von Helmholtz and Lord Kelvin, so perfectly produced electric and electro-magnetic waves, that these waves possess all the properties of luminous waves; the only distinguishing peculiarity is that their vibrations are less rapid than those of light.

It follows that one can reproduce with electric discharges the most delicate experiments of modern optics —reflection, refraction, diffraction, rectilinear, circular, elliptic polarisation, &c. But I must stop, gentlemen. I feel that I have assumed too weighty a task in endeavouring to enumerate the whole wealth which waves of transverse vibrations have to-day placed in our hands.

I said at the beginning that optics appeared to me to be the directing science in modern physics.

If any doubt can have arisen in your minds, I trust this impression has been effaced to give place to a sentiment of surprise and admiration in seeing all that the study of light has brought of new ideas on the mechanism of the forces of nature.

It has insensibly restored the Cartesian conception of a single medium refilling space, the seat of electrical, magnetic and luminous phenomena; it allows us to foresee that this medium is the depositary of the energy spread throughout the material world, the necessary vehicle of every force, the origin even of universal gravitation.

Such is the work accomplished by optics: it is perhaps the greatest thing of the century!

The study of the properties of waves, viewed in every aspect, is therefore, at the present moment, the most fertile study.

It is that which has been followed in the double capacity of geometer and physicist by Sir George Stokes, to whom we are about to pay so touching and deserved a homage. All his beautiful researches, both in hydrodynamics as well as in theoretical and practical optics, relate precisely to those transformations which various media impose on waves which traverse them.

In the many phenomena which he has discovered or analysed, movements of fluids, diffraction, interference, fluorescence, Röntgen rays, the dominant idea which I pointed out to you is always visible; it is that which makes the harmonious unity of the scientific life of Sir George Stokes.

The University of Cambridge may be proud of the Lucasian Chair of Mathematical Physics, because from Sir Isaac Newton up to Sir George Stokes it has contributed a glorious part towards the progress of Natural Philosophy! A. CORNU.

## NOTES.

WE are glad to be able to publish this week a translation of the Rede Lecture delivered at Cambridge by Prof. Alfred Cornu, professor of experimental physics in the École polytechnique, Paris, and a Foreign Member of the Royal Society, on the occasion of the recent celebration of the jubilee of Sir George Stokes as Lucasian professor of mathematical physics. Prof. Cornu delivered the lecture in French, and we are indebted to him for the translation of his brilliant discourse, which immediately precedes this Note.

AN interesting gathering took place at the Star and Garter Hotel, Richmond, on Thursday last, when a number of friends joined with the members of the Physiological Society in giving a congratulatory dinner to Sir John Burdon-Sanderson, Bart., F.R.S., and Prof. Michael Foster, K.C.B., Sec.R.S., in honour of Her Majesty's recent recognition of the great services they have rendered to science. The chair was taken by Prof. Schäfer, F.R.S., and the friends who assembled to support him in doing honour to the distinguished guests numbered considerably over a hundred. The principal speeches of the evening were made by the chairman, by Sir John Burdon-Sanderson, and by Prof. Michael Foster, all of whom were able to give interesting reminiscences of the early days of physiology in England, and of the great difficulties which used to be thrown in the way of those who wished to study the subject. Owing to the exigencies of the various examinations now in progress, many physiologists were unable to be present in the earlier part of the evening, but the great interest taken in the proceedings was shown by the long journeys undertaken by several in order that they might take part at the dinner.

THE special number of the *Atti*, containing the report of the anniversary meeting of the Reale Accademia dei Lincei, announces the annual awards of prizes. The Royal prize for astronomy for 1896 remains unawarded. The Royal prize for philology and languages is divided equally between Prof. Pio Rajna, for his critical edition of Dante's "De Vulgari Eloquentia," and Prof. Claudio Giacomino, for his studies on the Basque language. The prize for history and geography is unawarded, and the same is true of a prize offered for 1898 for perfecting the theory of motion of a rigid body. The Ministerial prize of 3400 lire for history for 1898 is divided, a prize of 1700 lire being awarded to Prof. Gaetano Salvemini, and smaller awards being made to Profs. Alberto Pirro, Niccolò Rodolico, and Michele Rosi. Of the Ministerial prize of 3400 lire for mathematics for 1898, a prize of 2000 lire is awarded to Prof. Ettore Bortolotti, and awards of 700 lire each are made to Profs. Federico Amodeo and Francesco Palatini. The adjudicators state that the works of Prof. Pirondini would have gained an award had not some of them received recognition on a previous occasion. The adjudicators of the Ministerial prize for philosophical and social sciences for 1897 award 500 lire each to Profs. Albino Nagy, Luigi Ambrosi, and Tarozzi. The Mantellini prize is unawarded. Of the Santoro prize for electro-technics one half is awarded to Signor R. Arnò, for his share in the joint invention with the late Prof. G. Ferraris of a new transformer. The Santoro prize for chemistry as applied to agriculture is unawarded, and from the Carpi prize for mathematical physics for 1897-8 a sum of 500 lire is awarded to Signor C. Canovetti, for his papers on the direction of aerostats and on the resistance of the air.

IN connection with the preparation of argon, a good deal of attention has been paid to the absorption of nitrogen by metals. Prof. Ramsay, it will be remembered, used magnesium. Later, lithium was proposed by Ouvrard, and a mixture of lime and magnesium by Maquenne. The subject has recently been systematically investigated by Dr. Hempel, who finds that a mixture of calcium magnesium and sodium is very much more effective than the agents just named. The mixture is obtained by using 1 gramme of finely divided magnesium, 5 grammes coarsely powdered lime, and 0·25 grammes sodium. In a comparative time experiment the rates of absorption of nitrogen by magnesium, lithium, lime-magnesium, and lime-magnesium-sodium were in the ratio 1, 5, 8 and 20.

TO commemorate the completion of the twenty-five years of active work as a teacher of physiology of Prof. Purser, of Trinity College, Dublin, a movement is on foot among the professor's former pupils to raise funds for the bestowment annually of a "Purser Medal" to the candidate who, in the half M.B. examination, shows the highest proficiency in physiology and histology. Subscriptions, which are not to exceed a guinea, should be forwarded to the honorary treasurer, Dr. W. J. Houghton, 30 Lower Fitzwilliam Street, Dublin.

DR. MAXWELL T. MASTERS, F.R.S., has been made an officer of the Order of Leopold by the King of the Belgians.

THE Neill Prize for 1895-98 has been awarded to Prof. J. Cossar Ewart, F.R.S., by the Royal Society, Edinburgh, for his experiments and investigations bearing on the theory of heredity.

THE King of Sweden has conferred upon Mr. E. P. Martin, past-President of the Iron and Steel Institute, a Knight-commandership of the Royal Order of Wasa, and upon Mr. Bennett H. Brough, present Secretary of the Institute, a Knighthood of the same Order.

A DEPUTATION from the Iron and Steel Institute, consisting of Sir W. C. Roberts-Austen, K.C.B., F.R.S., President, Sir Lowthian Bell, Bart., F.R.S., Mr. E. P. Martin, past-Presidents, and Mr. Bennett H. Brough, Secretary, waited upon the Queen last week for the purpose of presenting to Her Majesty an illuminated address and the Bessemer Gold Medal, in commemoration of the great progress made in the iron and steel trade during the Queen's reign.

THE Meteorological Council have appointed Captain Campbell M. Hepworth, R.N.R., to fill the post of Marine Superintendent in succession to the late Mr. Baillie. Captain Hepworth has been an observer for the Meteorological Office for twenty-three years, and almost all of his logs have been classed "excellent."

A MEETING of the Aeronautical Society will be held at the Society of Arts to-morrow (July 28) at eight p.m.

THE summer meeting of the Institution of Mechanical Engineers was opened at Plymouth on Tuesday. In connection

with the meeting the Freedom of the Borough of Devonport has been presented to the president, Sir W. H. White, K.C.B., F.R.S.

THE thirty-sixth annual conference of the British Pharmaceutical Society of Great Britain was opened on Tuesday at Plymouth, the president, Mr. J. C. C. Payne, Belfast, being in the chair. The executive committee reported that the total membership was 1303. A number of papers on technical subjects were read and discussed.

THE Japanese Government have, it is stated, decided to make vaccination compulsory in Japan. All children must be vaccinated before the age of ten months. The first re-vaccination is to take place at six, and the second at twelve years of age.

MR. C. J. LYONS, writing in the U.S. *Weather Review*, from Honolulu, points out that most prominent volcanic outbursts on Hawaii have occurred at times of minimum sun-spots; so that, if the connection is real, a great lava flow may be expected at some time between now and 1901. Whether the years of maximum sun-spots are coincident with the years of no eruption does not appear to have been examined by Mr. Lyons.

A REUTER telegram of July 21 from New York states that the crater on the peak of Mauna Loa, Hawaii, burst into violent eruption on the 4th inst. Lava flowed down in three streams, one going towards Hilo and the two others in the direction of the sea, threatening the coffee plantations and the sugar lands.

A SPECIMEN of the egg of the Great Auk was sold by auction at Stevens's Rooms last week, and, although slightly cracked, realised the sum of 300 guineas, which equals the amount paid for the specimen sold at the same place in 1894. The egg just sold was figured in the *Memoirs* of the Société Zoologique de France in 1888, and, with additional notes on its history, it appeared in the *Bulletin* of the Société in 1891.

THE *Astrophysical Journal* for June states that a conference of astronomers and astrophysicists will, on the invitation of Prof. Hale, be held at the Yerkes Observatory, Williams Bay, Wis., U.S.A., from September 6 to 8 next. In its plan and scope the conference will be similar to those held in 1897 and 1898 at Williams Bay and Cambridge, Mass., respectively. The committee charged with perfecting a plan for the organisation of a permanent society of astronomers and astrophysicists, to have charge of future conferences, will present its report.

ACCORDING to the *Athenaeum*, Dr. Sven Hedin has set out upon his new journey of exploration in Central Asia, and expects to be absent for about two and a half years, principally in East Turkestan and the northern part of Tibet. The Russian Government has accorded him free passage on the Russian railway and free transmission of his very extensive equipment. For his Asiatic travel, as in his earlier journeys, a guard of Cossacks is to be placed at his disposal upon his application where necessary.

THE annual meeting of the British Medical Association will be held at Portsmouth next week. The proceedings will commence on Tuesday, August 1, when Dr. J. Ward Cousins, Southsea, will deliver the presidential address in the town-hall. On Wednesday and following days the sections will meet in the mornings and afternoons. On Wednesday evening a *soirée*, invitations to which will be issued by the president, will be held in the town-hall, and on Thursday the annual dinner of the Association will be held in the same building, to be followed by a reception organised by the ladies' committee. On Friday night Alderman T. Scott Foster will give a ball at the town-hall. The meeting will be brought to a conclusion on Saturday evening, August 5.

WE learn from *Science* that Clark University, Worcester, Massachusetts, has just celebrated its decennial in a manner worthy of a university devoted to the advancement of science. The following lectures were delivered in connection with the celebration: Prof. Ludwig Boltzmann, of the University of Vienna, on the "Principles and Fundamental Equations of Mechanics"; Prof. Picard, of the University of Paris, on "Differential Equations," and on "Analytical Functions"; Prof. Angelo Mosso, of the University of Turin, on "The Relation between Muscular Exercise and the Development of Mental Power," and on "Bodily Disturbances accompanying the Emotions"; Prof. Santiago Ramon y Cajal, of the University of Madrid, on the "Structure of the Visual Cortex of the Human Brain," and Prof. August Forel, of Zürich, on "Hypnotism," and on "Arts."

AN International Congress of Physics, to be held during the Paris Exposition next year, is being organised by a Committee of the Société française de Physique. The congress will commence on August 6, 1900, and will last a week. Though a number of special congresses are being arranged, it is thought that a congress having for its object the discussion of fundamental questions of physical science will be of interest to all physicists. Among the subjects to be dealt with in reports and discussions are the definition of certain units, such as pressure, scale of hardness, quantity of heat, photometric values, constants of saccharimetry, spectrum scale, and electrical units not yet defined; bibliography of physics; and national laboratories. There will also be visits to exhibits of scientific interest in the Exposition, to laboratories and to manufactories; and conferences on some new subjects, to be announced later, will be arranged. The president of the organising committee is Prof. Cornu; vice-president, M. Cailletet; and secretaries, M. C. E. Guillaume (au Pavillon de Breteuil, Sèvres, Seine-et-Oise) and M. Lucien Poincaré (105 *bis* boulevard Raspail, Paris), the former being the secretary for foreign members, and the latter for France.

FROM the *Bulletin de la Société d'Encouragement* we learn that an International Congress of Applied Mechanics has been organised for 1900 in connection with the Universal Exhibition. A draft programme has already been drawn up, and the subjects for discussion include mechanical laboratories, mechanical applications of electricity, high-speed steam engines, the mechanics of motor cars and implements. The Congress will open on July 19, 1900, and will last a week. Full particulars are obtainable from the Secretary of the Commission, 44 rue de Rennes, Paris.

THE Berlin correspondent of the *Lancet* gives a few particulars concerning the institution for the study of tropical diseases, shortly to be erected in Hamburg by the Government. It was the wish of Prof. Koch and the medical faculty that the institution should find a home in Berlin, in connection with, and as a department of, the Institution for Infectious Diseases. The Government, however, was of opinion that Hamburg would be preferable because a large number of patients coming from tropical climates and suffering from the specific diseases of the tropics are received into the Hamburg hospitals. In this way the new institution will have ample material for study, whilst if the institution were established in Berlin the patients would have to be conveyed from Hamburg and other seaports to the metropolis, a proceeding which would eventually be prejudicial to them. It is neither decided yet when the institution will be opened nor who will be appointed director. Probably one of the Colonial medical officers will be placed in charge.

According to the *Journal of Applied Microscopy*, it is proposed to hold a bryological meeting at Columbus, Ohio, during the session of the American Association for the Advancement of Science at that place. It is intended to present a series of papers, illustrated by specimens, photographs, microscopical slides, books and pamphlets, and to show the work done by leading workers on the subject. In addition to these will be shown collections of specimens, macroscopic and microscopic, illustrating the monographic work of living American students, and foreign students who have worked on North American mosses will be asked to co-operate.

The weather was very warm and dry last week, and the thermometer reached a higher point than on any previous occasion this summer. At Greenwich there were five consecutive days on which the shade temperature exceeded 80°, and on Wednesday and Friday the thermometer exceeded 88°. In some of the London suburbs the air temperature was highest on Friday, the 21st, the thermometer in Stevenson's screen touching 90° in the south of the metropolis. The highest temperature in the sun's rays at Greenwich occurred on Wednesday, when the thermometer registered 158°, which is higher than any reading during the previous three years. A sharp thunderstorm passed over the metropolis on Sunday morning, and the accompanying rainfall was generally heavy. At Greenwich the fall of rain exceeded three-quarters of an inch, at Westminster an inch was measured, while at Brixton the rain amounted to half an inch, and in some localities it was even less. A cooler air has spread over the British Islands during the last few days, and the general type of weather is favourable to occasional showers, so that at length the recent drought may reasonably be considered at an end.

The United States *Monthly Weather Review* for March contains an interesting historical account of the meteorological services in Russia, and especially of the Central Physical Observatory, by Prof. Cleveland Abbe, from which we extract the following notes. This institution is dependent upon the Academy of Sciences, which was established by decree of Peter the Great, dated January 22, 1718, and its first public session was held on January 7, 1726. Prof. A. T. Kupffer, born in 1798, was the first director and organiser of the meteorological system in Russia; his first volume of "Observations météorologiques et magnétiques" was published in 1837. Subsequent issues attracted the attention of the Emperor, who ordered that the work should appear as an annual volume under the title "Annuaire magnétique et météorologique." These volumes appeared up to that for 1846, which was published in 1849. In the meantime (April 13, 1849) the Emperor established the Central Physical Observatory, and the *Annuaire* thereafter appeared under the title "Annales de l'Observatoire Physique Central," and these were published up to the time of Kupffer's death in 1865. Thereupon Prof. Kämtz (born 1801) was called from Dorpat; but he died in 1867. His successor was Prof. H. Wild, born at Zürich in 1833. He held the directorship until July 1895, when he resigned on account of health; but he still remains an honorary member of the Academy of Sciences of St. Petersburg. During his administration a great impetus was given to all meteorological and magnetical work, and the volumes of the *Annales* 1865-9 were edited by him. With the volume for 1870 a new series, under the title "Annalen des Physikalischen Observatoriums," was begun, and under his auspices the new observatory at Pavlovsk was established for the purpose of scientific investigation. The appointment of General Rykatcheff (who began working with Prof. Kämtz in 1866) as director of the meteorological service in 1895 marks a general change in the spirit of administration of affairs in Russia, where the so-called Russian element is at present predominant. The memoirs bearing on the work of the observatory are now published in Russian by the Physical Section of the Academy of Sciences; while the observations properly so-called, consisting entirely of numerical tables, are published in separate volumes under the former title of "Annales de l'Observatoire."

An ingenious machine for printing in colours, invented by Mr. Ivan Orloff, chief engineer and manager of the Russian Government printing works at St. Petersburg, has just been set up in London, and a company has been formed to develop the use of the machine for supplying coloured illustrations for periodicals and books. In colour printing by the ordinary method the successive colours are applied one at a time as the preceding one becomes dry. By means of the Orloff machine the whole of the colours required in a picture are printed at a single turn of the cylinder. If a picture has to be printed in, say, four colours, four separate blocks are arranged around the curved surface of the cylinder. As each block passes a particular point, the roller carrying the colour required by the block is made to fall upon it by a system of cams. Each block thus receives the coloured ink intended for it in the course of a revolution of the cylinder. All the printing surfaces, as soon as they are inked, transfer their designs to a composition roller which they pass, and this in turn transfers the combined coloured design to a final surface or *forme* carried on the same cylinder as the separate blocks, and from this *forme* the fully-coloured picture is imprinted upon paper at one impression. The fundamental idea of the machine is thus to print the separate colours in succession upon a common surface, and then to use the single surface as the *forme* in the final printing. These operations go on continuously. The cylinder completes one revolution in one-twentieth of a minute, within which time every colour surface has been inked and re-inked with its proper colour, and has delivered the result to the *forme* to be impressed upon paper. The results are very effective, and the "register" is perfect, no matter how many colours are used. The machine appears to mark a distinct development of methods of printing in colours.

From the *Standard* of July 22 we learn that the Botanical Garden of the Vienna University can now boast of possessing specimens of a plant not to be found in any similar institution in the world, or, indeed, anywhere else in Europe or America. When the Austrian Expedition to Southern Arabia, under Prof. Dr. David Heinrich Müller, was out there last winter, Prof. Dr. Oskar Simony, son of the well-known geographer, succeeded in obtaining some incense bushes, notwithstanding that the Arabs keep the places where they grow a secret from Europeans. He brought them to Vienna alive, and they are now in full leaf.

In the *Mathematical Gazette* for June, published under the auspices of the Mathematical Association, Prof. F. Morley communicates a note on the sphero-conic, in which he gives a simplified proof of the bifocal property. Mr. S. A. Saunders calls attention to the paradoxical questions arising from the notion of motion *at* an instant, a conception which like pressure *at* a point involves a peculiar use of the word "at." Mr. R. F. Davis contributes a paper on "Porismatic Equations"; and there is the usual collection of problems and solutions and reviews of text-books.

Only one article in the new part of the *Quarterly Review* is of scientific interest; it deals with the important subject of climate and colonisation. The writer of the article, after surveying a selection of the literature of the subject, and commenting on the efforts that have been or are being made towards a better understanding of tropical diseases, says: "Europeans who settle in tropical countries must not expect to remain unchanged from generation to generation. Even when there is no intercrossing, although the main features may persist for a long while, the new surroundings gradually give their own

impress. In all countries where Europeans have settled, we find they have altered in temperament, ideas, and bodily features. The change is slow at first, because fresh blood constantly streams in from the mother country and perpetuates the original characters; but as the Colony grows older the immigration falls off, and the new settlers diverge further and further from the original type. We have no reason to dread this evolution; it is the outcome of adaptation; and when we consider the splendid physical characteristics of many of the native races which inhabit tropical regions, we may fairly conclude that such adaptation will lead to the development of new types no whit inferior to the old. When we further consider that man, modifying the environment and substituting his selection for that of nature, has been able to produce and to develop endless varieties of domestic animals which would never have come into existence under natural conditions, and would soon deteriorate or perish when out of their artificial surroundings, we may certainly believe that he can, by taking thought, escape many of those detrimental influences which irresistibly modify all other organic beings."

"THE Geology of the Coolgardie Goldfield" forms the subject of the third *Bulletin* of the Geological Survey of Western Australia, and it is written by Mr. Torrington Blatchford, Assistant Government Geologist. This goldfield was discovered in 1892, and in the course of six years over two thousand tons of ore have been crushed, yielding gold at the rate of 1 oz. 3 dwt. per ton. This has been derived mainly from quartz reefs and partly from "lode formations." The amount of gold obtained from the rich alluvial deposits has not been estimated. The district of Coolgardie consists of a mass of granite on the west, succeeded by a belt of hornblendic and talcose schists, the whole being intersected by igneous dykes. Recent superficial deposits cover a large portion of the field, and at the base of these there is in places a thin stratum of "cement," an auriferous conglomerate that has not yet proved of much economic value. Gold is found in pyrites in the altered schists bordering the acid dykes, and the material is traversed by numerous small quartz leaders forming "stockworks." Though much gold has been won from this source, the lodes are small and irregular. The quartz reefs occur principally in the schists, and they dip from 60° to 80° to the east. The water-supply of the region is a source of trouble and expense. With a rainfall of only seven inches no great supply can be expected, except by storing. Shallow wells yield limited supplies up to 4000 gallons per diem at a depth of 200 feet, but a good deal of the underground water is saline. Deep boring has been unsuccessful, and supplies have in some cases to be brought from a distance. An excellent coloured geological map, on a scale of an inch to forty chains, has been prepared by Mr. Blatchford and Mr. E. L. Allhusen. This is an index to a larger map which is published separately.

IN the *Philosophical Magazine* for July the Rev. O. Fisher deals with the residual effect of a former glacial epoch upon underground temperatures. The object of the paper is to examine whether traces of the effects left by a former glacial period upon underground temperatures are sufficient in amount to enable estimates to be made, from observations in deep wells and mines, of the lapse of time since the ice disappeared from the land. The author investigates the character of the traces which a former glaciation might be expected to leave behind, the principal one being a reduction of the gradient. From observations of the temperature of a well at Wheeling, U.S.A., combined with a certain assumption, the author estimates the time of the glacial period at 34,013 years. On the whole, however, he considers that the question as to whether there is any prospect of estimating the date of the glacial epoch from underground temperatures must be answered in the negative; nevertheless, the different gradients observed in different localities may possibly be attributable in a measure to glaciation.

IN No. 8 of the series of *Frammenti concernanti la geofisica* (Rome) Dr. Folgheraiter gives an interesting account of the singular magnetic effects produced by lightning on a house at Torre Nuova, which was struck on April 8 last. The observations led the author to conclude (1) that the lightning produced a large number of singular points and zones in the masonry, it being inadmissible that the individual stones should have been so highly magnetised before construction of the walls; (2) that while doubts have hitherto existed as to the possible formation of singular points in tufa, this question has now been answered in the affirmative; (3) the alternation in the polarities of the singular points and zones, even on the same piece of tufa, is noteworthy, but no connection has yet been established between these alternations and the mode of propagation of the electricity; (4) it is now amply proved that lightning produces marked magnetisation independently of the inductive action of terrestrial magnetism.

WE have received a paper by the Rev. F. S. Chevalier, S.J., published by the Zi-ka-Wei Observatory, on the navigation of the Upper Yang-tze. The author's knowledge of the river is chiefly derived from personal observation made during a voyage as far up as Ping-shan-hsien during the winter of 1897–98. He takes a much more hopeful view of the navigability of the Upper Yang-tze than did Lieut. Dawson, whose survey is reported on in the *China Sea Directory*. The three chief obstacles, in the form of rapids, are discussed in detail, and suggestions are made with the view of making their navigation practicable. M. Chevalier has in preparation a chart of the river from I-chang to his highest point, on a scale of 1/25,000.

THE debatable question of the diffraction of Röntgen rays forms the subject of some recent experiments described by Prof. H. Haga and Dr. C. H. Wind in the *Proceedings* of the Royal Academy of Sciences of Amsterdam. In such experiments it is better, in order to obtain greater intensity, to use narrow slits than to make the distances great. As the time of exposure varied from 29 to 200 hours, the apparatus had to be mounted on a heavy freestone block supported on the central pillar of the Physical Laboratory of the University of Groningen, where the experiments were made. The diffraction slit was 3 cm. high and 14 microns at the upper end, gradually narrowing to a width of a few microns. A careful examination shows a kind of broadening out of the image corresponding to the narrowing of the slit, and this it is considered can only be attributed to diffraction of the Röntgen rays. The authors give estimates of the wave-lengths of the rays lying between 0,12 and 2,7 Ångström units, but consider that they cannot succeed in making measurements instead of estimations of the wave-length until Röntgen tubes have been produced remaining in working order as long as those used, and giving out rays of much greater energy.

THOSE responsible for the "Guide to the Museum of Eton College," seem remarkably fond of displaying an acquaintance with technical terms. Why, for instance, in giving a list of the birds of Berkshire, was it necessary to encumber it with the subheadings "Neornithes," and "Carinatæ," seeing that all existing birds come under the former category, and all those of Europe under the latter? If the number of names were reduced, and the language somewhat simplified throughout, the *Guide* would be admirable for its purpose. The museum appears to be well arranged; and it is satisfactory to note that the authorities recognise the importance of making the local collection the most prominent feature.

THE report of the Magnetical and Meteorological Observations made at the Government Observatory, Bombay, for the year 1897 has just been issued, with an appendix.

MESSRS. ISENTHAL, POTZLER, AND CO., of Mortimer Street, have sent us a supplementary list of new radiographic instruments made by them. Attention is drawn to several pieces of apparatus of recent construction.

WE have received the prospectus of the "One and All" Flower-show, an exhibition of horticultural photographs, to be held at the Crystal Palace on August 14–19, under the auspices of the "Agricultural and Horticultural Association, Limited."

IN the number of the *Biologisches Centralblatt* for July 1, Dr. R. Keller finishes his review of recent advances in vegetable physiology and botany; and Dr. G. Lindner his account of the germs of Protozoa found in rain water.

THE *Cambridge University Reporter* for June 22 contains the annual report of the Botanic Garden Syndicate for the year 1898. Several interesting and important additions have been made to the Botanic Garden during the year.

IN the numbers of the *Agricultural Gazette of New South Wales* for May and June is a continuation of M. A. O'Callaghan's series of papers on dairy bacteriology. It contains a report, with illustrations, of the bacteriological condition of a number of butters produced in the Colony.

THE Trinidad *Bulletin of Miscellaneous Information* (Botanical Department, No. 19) contains a preliminary report by Mr. G. Massee on the cacao pod disease, which is rife in the Colony. Mr. Massee ascribes it to a fungus belonging to the Peronosporeæ.

IN the *Irish Naturalist* for July is a synopsis of the Irish Characeæ, by Prof. T. Johnson; a paper on some algæ from the Antrim coast, by H. Hanna; and one on some freshwater mites from Co. Dublin, by D. Freeman.

THE *Transactions* of the Manchester Microscopical Society contains several papers which show a record of good work in microscopy:—The genitalia and radulæ of the British Hyalinia, by W. Moss; *Peripatus Leuckarti*, by F. Paulden; Scale insects, by A. T. Gillanders; *Myriothela Phrygia*, a tubularian hydroid, by W. Blackburn; and others.

WE have received a copy of Dr. Gunnar Andersson's "Studies of the Quaternary Flora of Finland" (*Bulletin de la Commission Géol. de Finlande, Helsingfors*, 1898). The work is accompanied by four excellent plates of fossil seeds, and it contains descriptions and sections of the peaty deposits from which they have been obtained.

THE current issue of the *Reliquary and Illustrated Archaeologist* contains many interesting contributions, among which may be mentioned "Antiquities of Bolsterstone and Neighbourhood," "The Instrument of the Rosary," "Two Midlothian Souterrains," "The Grinlow Barrow, Buxton," and "Notes on Archæology and Kindred Subjects." As is usual in this magazine the articles are well illustrated.

MR. ARTHUR S. EAKLE describes some andesites from the Fiji Islands (*Proc. Amer. Acad. Arts and Sciences*, May 1899). Augite-andesite seems to be the predominating rock of the islands, and it varies from types having a small amount of augite with a large amount of felspar, and with biotite as an accessory, to those in which augite is the dominant constituent, thus showing a gradation into basalt.

VOL. II., part 6, of the serial form of C. E. Groves's translation of Fresenius' "Quantitative Analysis" has now been brought out by Messrs. J. and A. Churchill; the University Correspondence College has issued its Matriculation Directory dated June 1899, in which will be found articles on the special subjects for January and June 1900; a new edition of "The Arithmetic of Electrical Measurements," by W. R. P. Hobbs, has been issued by Murby. The work has been revised and in part re-written.

THE additions to the Zoological Society's Gardens during the past week include an Anubis Baboon (*Cynocephalus anubis*, ♀) from Accra, presented by Mr. G. B. Haddon Smith; a Feline Dourocouli (*Nyctipithecus vociferans*) from Brazil, presented by Mrs. Arthur Harter; a Ring-tailed Lemur (*Lemur catta*) from Madagascar, presented by Mrs. T. Butt Miller; a Spotted Ichneumon (*Herpestes auro-punctatus*) from Malacca, presented by Mr Geo. F. Aress; a Levaillant's Cynictis (*Cynictis penicillata*), two Bristly Ground Squirrels (*Xerus setosus*) from South Africa, presented by Mr. J. E. Matcham; a Common Duiker (*Cephalophus grimmi*, ♂) from South Africa, presented by Captain G. C. Denton; two Cormorants (*Phalacrocorax carbo*) from Scotland, presented by Mr. P. L. Pemberton; a Ground Hornbill (*Bucorvus abyssinicus*) from West Africa, presented by Mr. Geo. Hirst; two Blood-rumped Parrakeets (*Psephotus haematonotus*) from Australia, presented by Mrs. A. Chambers; a Golden Eagle (*Aquila chrysaetus*) from Scotland, presented by Mr. H. C. Ross; three Adorned Terrapins (*Chrysemys ornata*) from Mexico, presented by Mr. C. J. Rickards; a Burchell's Zebra (*Equus burchelli*, ♀) from South Africa, two Hairy Armadillos (*Dasypus villosus*) from La Plata, a Lion Marmoset (*Midas rosalia*) from South-east Brazil, a Blue-fronted Amazon (*Chrysotis aestiva*) from South America, deposited; a Chattering Lory (*Lorius garrulus*) from Moluccas, purchased; two Collared Fruit Bats (*Cynonycteris collaris*), a Burrhel Wild Sheep (*Ovis burrhel*), born in the Gardens.

## OUR ASTRONOMICAL COLUMN.

ASTRONOMICAL OCCURRENCES IN AUGUST:—

August 2. 11h. 25m. Minimum of Algol ($\beta$ Persei).
11. Maximum of the August meteoric shower of Perseids.
14. 8h. 25m. to 9h. 37m. Occultation of the star D.M. − 22°, 3989 (mag. 6) by the moon.
14. 9h. 4m. Transit (immersion) of Jupiter's Sat. III.
15. Illuminated portion of the disc of Venus 0·989, of Mars 0·949.
18. 10h. 28m. to 11h. 34m. Occultation of *f* Sagittarii (mag. 5·1) by the moon.
22. 9h. 21m. to 10h. 15m. Occultation of 16 Piscium (mag. 5·6) by the moon.
22. 15h. 1m. to 16h. 8m. Occultation of 19 Piscium (mag. 5·2) by the moon.
23. Outer minor axis of Saturn's outer ring = 17″·94.
25. 9h. 57m. Minimum of Algol ($\beta$ Persei).
26. 12h. 5m. to 13h. 5m. Occultation of $\tau^2$ Arietis (mag. 5·2) by the moon.
26. 12h. 55m. to 13h. 51m. Occultation of 65 Arietis (mag. 5·6) by the moon.
27. 16h. 20m. to 17h. 19m. Occultation of $v^1$ Tauri (mag. 4·6) by the moon.
27. 16h. 49m. to 18h. 9m. Occultation of $v^2$ Tauri (mag. 5·5) by the moon.
29. 16h. 9m. to 17h. 25m. Occultation of $\eta$ Geminorum (mag. variable) by the moon.
30. 14h. 59m. to 15h. 58m. Occultation of $\zeta$ Geminorum (mag. variable) by the moon.

TEMPEL'S COMET 1899 *c* (1873 II.).

*Ephemeris for 12h. Paris Mean Time.*

| 1899. | R.A. h. m. s. | Decl. ° ′ ″ | Br. |
|---|---|---|---|
| July 27 | 20 47 55·4 | −21 56 9 | 3·698 |
| 28 | 49 6·7 | 22 29 17 | |
| 29 | 50 18·0 | 23 2 17 | |
| 30 | 51 29·2 | 23 35 4 | |
| 31 | 52 40·5 | 24 7 36 | 3·673 |

| 3 | 20 56 14·6 | −25 43 7 | |

The comet is now as bright as it is expected to become according to computation, and moreover is rapidly moving southwards, so that it will soon be beyond the reach of observers in these latitudes. During the week it passes from a position near the 6th mag. star 17 Capricorni to the vicinity of the 4th mag. red star A Capricorni.

Stellar and Nebular Spectra with Concave Grating.—In the earlier part of 1898 Messrs. Poor and Mitchell described the results of their attempts to photograph stellar spectra with a Rowland concave grating (*Astro-Physical Journal*, 8, p. 157). The grating used was a small one, having a ruled surface of only 1 × 2 inches with 15,000 lines to the inch, the radius of curvature being about 1 metre. Later a special grating was made with a ruled surface $2 \times 5\frac{3}{4}$ inches, having 7219 lines to the inch. The radius of curvature of this was also 1 metre. The instrument was mounted on the 9·3-inch Hasting's refractor as guiding telescope, and the results obtained were very promising, although the observatory is on the *sixth* floor of the Physical Laboratory at Baltimore. In November 1898, however, by the kindness of Prof. Hale, it became possible for Mr. Mitchell to mount the grating on the 12-inch Brashear refractor of the Verkes Observatory (*Astro Physical Journal*, x. pp. 29–39, 1899). It will be remembered that the grating is used "*direct*," the concave surface bringing the diffracted beam from the star to focus on the plate, and that a considerable advantage obtains in that the spectra obtained are *normal.* The grating was so oriented that the lines were parallel to the equator, so that irregularities in the driving-clock should have no effect on the definition. The astigmatism alone not being sufficient to give the spectrum sufficient width, this was effected by allowing the star to trail in right ascension. Photographs of the spectra of a large number of stars have been thus obtained, with exposures varying from 5 to 60 minutes. These are given in a table in the article. Of special interest is the fact that these photographs show the ultra-violet region remarkably well, as is to be understood when it is remembered that the light has to traverse neither lenses, prism trains nor slit. The photograph of Sirius showed about 75 lines between $H\beta$ and $H\gamma$, and in the ultra-violet 21 lines of the series due to hydrogen were measured.

In February two very interesting photographs of the spectrum of the Orion nebula were obtained with exposures of about 200 minutes. Just as with an objective prism, these spectra consist of a series of images of the nebula, the measures of corresponding regions of which give the wave-lengths of the various lines they represent.

With the grating used, the length of the photographic region in the first order was about $1\frac{1}{4}$ inches, using Seed's gilt edge plates. In the second order the distance from $H\beta$ to $H\gamma$ was 0·6 inch, and from $H\beta$ in the first order to $H\beta$ in the second was 2·8 inches. The photographic plate used, 1 × 5 inches, thus included both spectra, and their duplicate measurement afforded a definite control over the wave-lengths determined.

Attention is directed to the fact that the spectra being *normal*, absolute measurements of wave-length, and therefore of motion in line of sight, may be determined when larger instruments of this kind are available. A grating with ruled surface 10 × 15 inches would probably be fully equal in performance to any spectroscopes in present use.

## *THE REASON FOR THE HISSING OF THE ELECTRIC ARC.*[1]

### II.

And now we come to the most important of all the changes that take place when the arc begins to hiss, viz. the alteration in the shape of the *positive* carbon.

During the course of his 1889 experiments, Luggin (*Wien Sitzungsberichte*, 1889, vol. xcviii. p. 1192) observed that the arc hissed when the crater filled the whole of the end of the positive carbon. He was thus the first to call attention to the fact that there was a direct connection between hissing and the relation between the area of the crater and the cross-section of the tip of the positive carbon. My own observations in 1893 led to a conclusion somewhat similar to Luggin's, but yet differing in an important particular. It seemed to me that, with hissing arcs, the crater always *more* than covered the end of the positive carbon—that it overflowed, as it were, along the side. How far this is true will be seen from an examination of Figs. 4, 5, 6 and 7, which show the shaping of the carbons under various conditions with silent and hissing arcs. These figures have all been made from tracings of the images of actual normal arcs, burning between carbons of various sizes, and they were carefully chosen with special reference to the shaping of the positive carbons. For, with normal arcs, the shape of the end of a positive carbon, even taken quite apart from that of the negative carbon and of the vaporous arc itself, is capable of revealing almost the whole of the conditions under which the arc was burning when it was formed. It is possible, for instance, with a normal arc, to tell, from a mere drawing of the outline of the positive carbon and of its crater, whether the arc with which it was formed had been open or enclosed, short or long, silent or hissing, burning with a large or with a small current for the size of the carbon.

Take, for example, Fig. 4 (see p. 285, July 20), and note the difference in the shape of the positive carbon with a current of 3·5 amperes, as in (*a*), and with one of 34 amperes, as in (*b*). In the first case the tip of the positive carbon is rounded, so that the crater lies in its smallest cross-section; in the second, the tip would be practically cylindrical for some distance, but that the crater has burnt away a part of the cylinder, making the tip look as if it had been sheared off obliquely. Comparing now the tips of the positive carbons when the arc is silent and when it is hissing in all the four figures, 4, 5, 6, 7, we find the same difference. With all the silent arcs the tip is more or less rounded, and the crater lies in its smallest cross-section, and consequently is less in area than any but the smallest cross-section. With all the hissing arcs, on the other hand, the tip of the positive carbon is practically cylindrical for a short distance at least, or would be but that it is sheared away by the crater; consequently the area of the crater is *greater* than the smallest cross-section of the tip, or, indeed, than the cross-section of the tip for some little distance along its length.

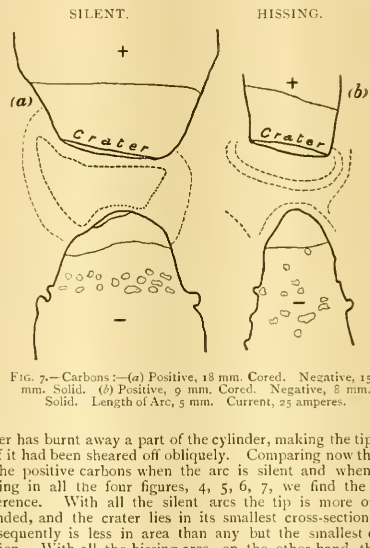

Fig. 7.—Carbons:—(*a*) Positive, 18 mm. Cored. Negative, 15 mm. Solid. (*b*) Positive, 9 mm. Cored. Negative, 8 mm. Solid. Length of Arc, 5 mm. Current, 25 amperes.

We have now arrived at the real, the *crucial*, distinction between a silent and a hissing arc. When the crater occupies the *end* of the positive carbon only, the arc is *silent*; when it not only covers the end, but also extends up the *side*, the arc *hisses*. Hence, the arc must be at the *hissing point* when the smallest increase in the area of the crater will make it begin to cover the *side* of the positive carbon, and this can only be when the tip of that carbon has very nearly the same cross-section for some little distance from its end—in other words, when its sides are nearly vertical.

I shall now proceed to show that the extension of the crater up the side of the positive carbon is not the *effect* but the *cause* of hissing; that, in fact, *hissing is produced by the crater be-*

[1] Based on a paper read before the Institution of Electrical Engineers by Mrs. W. E. Ayrton. (Continued from page 286.)

*coming too large to occupy the end only of the positive carbon, and therefore extending up its side.*

Simple as is this explanation of a very complicated series of phenomena, it is the true one; but before proceeding to demonstrate its truth it will be interesting to see how the laws for the largest silent currents with normal arcs, which have already been obtained from the electrical measurements on pp. 283, 284, may be deduced on the above hypothesis from Figs. 6 and 7.

In Fig. 6 (p. 285) we have a series of four normal arcs of the same length burning between solid carbons of the same diameter; but in (*a*) the current is 6 amperes, in (*b*) 12, in (*c*) 20, and in (*d*) 30 amperes. The bluntness of the tip of the positive carbon may be measured by the obtuseness of the angle A B C. In (*a*) the tip is very blunt, and the area of the crater is certainly less than any but its smallest cross-section; therefore the arc is certainly silent. In (*b*) the tip is less blunt, but the arc is still evidently silent; in (*c*) the angle A B C is much more nearly a right angle, and it is plain that a very small increase in the area of the crater would cause it to burn up the side of the tip; therefore the arc is near the hissing point. In (*d*) the angle A B C is practically a right angle, the tip of the positive carbon is cylindrical, and the crater has evidently burnt partly up its side. Thus with a normal arc, keeping the length of the arc constant and gradually increasing the current, must bring us to a hissing point.

This brings me to the reason for the great importance of distinguishing between arcs that are normal and those that are not. For although, with normal arcs of any given length, hissing only starts when the current is *greater* than it can be with any silent arc of the same length, with a *non*-normal arc of 2 mm. I have been able to produce hissing with a current of 11 amperes, and to have a silent arc burning with a current of 28 amperes, the same carbons being used in each case.

The reason of this is obvious. When the arc is normal, the carbon ends and crater have a perfectly definite size and shape corresponding with each current and length of arc, and changes in these are made slowly, so as to allow time for the carbons to assume their proper form in each case. If, however, the current be *suddenly* much increased, when, say, the carbons have previously been very pointed, then the area of the crater may increase so rapidly that it will extend up the side of the carbon and cause hissing, even although the carbons would have shaped themselves so that there would have been room for the crater to remain at the end of the carbon if the change had been made more gradually.

Suppose, for instance, the end of the positive carbon were filed to a long fine point, then a very small current would make a crater large enough to extend up the side of the point, and produce a hissing arc. If, on the contrary, the end were filed flat, so as to have as large a cross-section as possible, quite a considerable current could flow silently even with a short arc, for in that case it would require the current to be very great for the crater to be large enough to fill up the whole of the end of the positive carbon.

Next, I have shown elsewhere (*The Electrician*, 1895, vol. xxxiv. p. 614) that, with a constant current, the end of the positive carbon becomes rounder and blunter, and occupies a larger portion of the entire cross-section of the carbon rod, the more the carbons are separated. Hence the longer the arc the greater must be the area of the crater, and consequently the greater must be the current, before the crater extends up the side of the positive carbon. Consequently, the longer the arc the greater is the largest silent current.

Thirdly, it follows that when the current and the length of the arc have been increased to such an extent that the round, blunt tip of the positive carbon occupies the whole cross-section of the carbon rod itself, no further increase in the size of the crater is possible without a part of it extending up the side of the carbon. Hence the largest silent current for a positive carbon of a particular diameter cannot exceed a particular value, however long the arc may be made. And lastly, similar reasoning, used in conjunction with Fig. 7, tells us that the thicker the positive carbon the greater must be the largest current that can flow silently with a particular length of arc, which was one of the results deduced from the curves in Figs. 2 and 3.

Thus the fact that hissing occurs when the crater covers more than the end surface of the positive carbon and extends up its side, combined with our knowledge of the way in which the positive carbon shapes itself in practice, is sufficient to enable us to deduce *all* the laws given on pp. 283, 284 which govern the largest current that will flow silently with the *normal* arc under given conditions.

We come now to the question, why should the arc hiss when the crater burns up the side of the positive carbon—what happens then that has not happened previously?

In pondering over this question, the possibility occurred to me that as long as the crater occupied only the *end* surface of the positive carbon it might be protected from direct contact with the air by the carbon vapour surrounding it, but that, when the crater overlapped the side, the air could penetrate to it immediately, thus causing a part at least of its surface to *burn* instead of volatilising. Many circumstances at once seemed to combine to show that this was the true explanation. The dancing circles I observed, and Mr. Trotter's stroboscopic images, how were they caused but by draughts getting into the arc? Then the humming noise, which sounds like the wind blowing through a crack, was not this probably caused by the air rushing through a slight breach in the crater, already getting near to the critical size? This air pouring in faster and faster as the breach widened would cause the arc to rotate faster and faster, sometimes in one direction, sometimes in another, according as the draught was blown from one side or the other. Then, finally, the air would actually reach the crater, burn in contact with it, and the P.D. would fall and the arc would hiss.

In the open arc, whether silent or hissing, the outer envelope of the vaporous portion is always bright green. With the hissing arc the light issuing from the *crater* is also bright green or greenish blue. What so likely as that the two green lights should have a common origin, viz. the combination of carbon with air? For the outer green light is seen just at the junction of the carbons and carbon vapour with the air, and the inner one only appears when air can get direct to the crater.

Again, why does the arc always hiss when it is first struck? Is it not because a certain amount of air must always cling to both carbons when they are cold, so that when the crater is first made its surface must combine with this air?

The cloud that draws in round the crater when hissing begins would be a dulness caused by the air cooling the part of the crater with which it first came into contact, the bright spots being at the part where the crater and air were actually burning together. In fact everything seemed to point to the direct contact of crater and air as being the cause of hissing and its attendant phenomena.

One easy and obvious method of testing this theory immediately presented itself. If air were the cause, exclude the air, and there would be no sudden diminution of the P.D. between the carbons, however great a current might be used. Accordingly I tried maintaining arcs of different lengths in an enclosed vessel, and increasing the current up to some 40 amperes. *No* sudden diminution of the P.D. could be observed with any of the currents or lengths of arc employed, although when the same carbons were used to produce *open* arcs, the sudden diminution of 10 volts in the P.D. between the carbons occurred with a current as low as 14 amperes for a 1 mm. arc.

It was, of course, impossible, in these experiments, to avail myself of an ordinary enclosed arc lamp, such as is used for street lighting, since a current of only some 5 or 8 amperes is all that is used with such a lamp, whereas to test my theory it was necessary to employ currents up to 40 amperes. Accordingly I constructed little electric furnaces of different kinds, one of which is shown in Fig. 8.

Some curves connecting the P.D. between the carbons with the current when the arc was completely enclosed in the crucible (Fig. 8) are given in Fig. 9. The carbons were similar to those used with the open arc experiments (Fig. 1, p. 282), being solid, the positive 11 mm. and the negative 9 mm. in diameter. As this crucible—the first one made—had no window, the length of the arc could not be kept quite constant, but the distance by which the carbons were separated was noted at the beginning of the experiment, and they were then allowed to burn away, without being moved, till the end, when the distance the positive carbon had to be moved in order to bring it tightly against the negative was noted. Measured in this way, the length of the arc was 1·5 mm at the beginning and 2 mm. at the end of the experiment. The current was started at 6 amperes, and gradually increased to 39 amperes; then as gradually diminished to 6 amperes again, increased to 36 amperes, and diminished to 5 amperes, when the arc was extinguished. The

P.D. between the carbons for a given current seems to have increased as the length of time during which the arc had been burning increased; this was undoubtedly partly due to the lengthening of the arc, but was probably also partly due to the whole of the air in the pot having been gradually burnt up or driven out through the slag wool and the asbestos ring by the pressure of the carbon vapour.

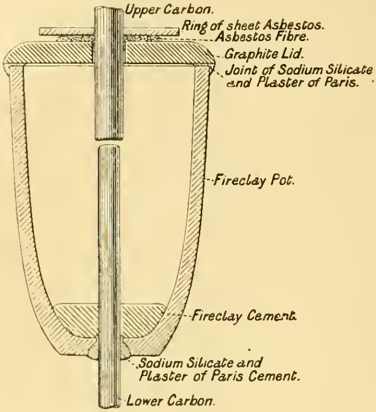

FIG. 8.

Many other sets of curves were obtained, but all with the same result, viz. that when once the crucible had been freed from air, no sudden diminution in the P.D. could be observed on increasing the current far beyond the value at which this diminution occurred on lifting up the lid and allowing the air to have access to the arc.

The next thing to do was to try if an open arc could be made to hiss and the P.D. to diminish suddenly by blowing air at the lege, suggested using a tubular positive carbon and blowing the air down it. This plan answered admirably, for when a current of 10 amperes was flowing with an arc of about 3 mm., so that the arc was quite silent, each puff of air blown down through the positive carbon was followed by a hiss and the characteristic diminution of the P.D. between the carbons. With a current of 6 amperes, however, I could get no hiss, but simply blew the arc out each time, probably because, with such a small current, the arc was cooled sufficiently to be extinguished before the action could take place.

Oxygen was next tried, still with the open arc, and again each puff produced a hiss and diminution of the P.D., the latter being exactly the same in amount as when air was used, namely, about 10 volts. As my idea was that the diminution of the P.D. was due to the chemical combination of air with carbon at the temperature of the crater, the fact of oxygen producing the same diminution as air seemed to show that nitrogen would produce no effect, and that all the effect produced by air was due to the oxygen in it. Accordingly I tried blowing nitrogen down the positive carbon of an open arc, and found that *no* change in the P.D. followed if the nitrogen was blown through gently, but that, beyond a certain pressure, the arc was blown to one side, and thus lengthened, so that the P.D. *rose* as it always does when the arc is lengthened, and, if the pressure continued, the arc went out.

This experiment proved two things—firstly, that it is the *oxygen* in the air that causes the diminution in the P.D. with hissing; secondly, that this diminution is not due to cooling, for nitrogen would cool the arc as effectually as oxygen or air.

To make assurance doubly sure on this point, carbon dioxide was blown down the tubular positive carbon, with the same result as when nitrogen was used, viz. no change was produced in the P.D. between the carbons unless the pressure of the gaseous stream were large enough to blow the arc on one side, and then an increase and not a diminution in the P.D. was observed.

If, however, the current was *very near* the value that made an open arc of the particular length used start hissing, blowing either nitrogen or carbon dioxide through the positive carbon sometimes started hissing; but this was due, *not* to any direct action of the stream of gas on the carbon, but to the arc being deflected by the gaseous stream and burning obliquely up the side of the carbon, and thus allowing the air to come into contact with the crater. The proof of this was that this diminution in the P.D. had the same value as if air had been

ARC ENCLOSED IN CRUCIBLE.

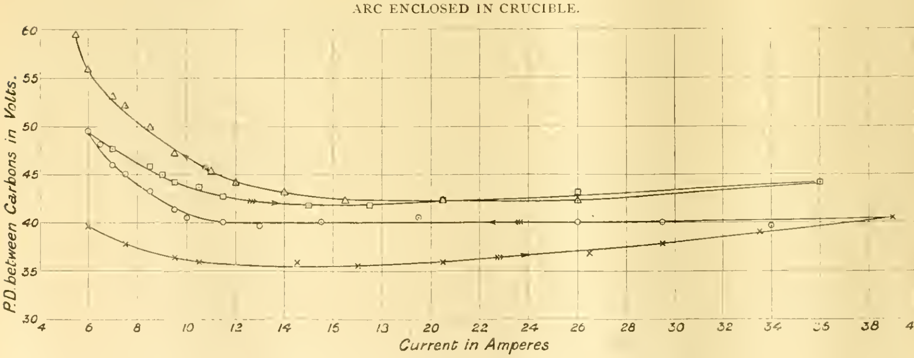

FIG. 9.—Curves connecting P.D. and Current for nearly Constant Length of Arc of 1·5 mm. to 2 mm. The arrows show the direction in which the Current was varied. Carbons:—Positive, 11 mm. Solid; Negative, 9 mm. Solid.

crater, when the current was so small that the crater remained well at the end of the positive carbon—in fact, to bring the air in contact with the crater artificially when a much smaller current was flowing than would usually produce hissing. I first tried inserting a carbon tube in the arc, and blowing through it, but this almost invariably blew the arc out. Then Mr. Phillips, one of Prof. Ayrton's assistants at the Central Technical Col- employed, and that the hissing did not cease when the stream of nitrogen or of carbon dioxide was stopped.

This was not the case with hydrogen, however. When that gas was blown down the positive carbon in the open air, the arc would start hissing, if the current were large enough, *and stop hissing the moment the hydrogen was shut off.* Not only this, but the diminution in the P.D. had a different value from

that produced by air, being only about 6·6 volts, or about $3\frac{1}{2}$ volts lower than when the hissing was caused by air alone.

In order to exclude all possibility of doubt as to the effect of the various gases, I repeated the experiments with the arc entirely enclosed in one of the fire-clay crucibles, so that the only gases that could reach the crater were those blown down the tubular positive carbon. The current was distinctly below the hissing point, being only 10 or 11 amperes, and the arc was from 2 mm. to 3 mm. long.

The results were exactly the same as with the open arc, except in the case of hydrogen. For air and oxygen produced hissing and a sudden diminution of the P.D., and nitrogen and carbon dioxide had no such effect, even when the current was very much increased. But whereas, as has been previously stated, hydrogen produced a distinct hissing of its own when blown down the positive carbon in the *open air*, it produced *none* when used in the same way with the arc *enclosed* in the crucible.

To prove that, in order to produce the sudden diminution of P.D under discussion, it was necessary for the active gas to actually *touch* the crater, a tubular *negative* carbon was used, and each gas was blown up through it in turn, gently enough not to force the gas directly against the crater.

In *no* case was there any sudden diminution of the P.D., whatever gas was employed, and whether the arc was open or enclosed. On the contrary, there was generally a small increase, probably due to the lengthening of the arc by its being blown on one side. If oxygen or air were blown *very hard* up the negative carbon, they would either produce hissing, or blow the arc out, or both; for in that case some of the gas got to the crater uncombined with the carbon vapour, and acted exactly as if it had been blown do ·n the tubular positive carbon.

The case, then, stands thus:

(1) When the arc begins to hiss in the ordinary way, the P.D. between the carbons diminishes by about 10 volts.

(2) If the air is excluded from the arc, this diminution of the P.D. does not take place, even when the current is nearly three times as great as would cause hissing in the air.

(3) If, however, while the air is excluded, puffs of air are sent against the crater, the diminution of the P.D. *does* occur, even with currents much *smaller* than would cause hissing in the air.

(4) If, instead of air, *oxygen* is sent against the crater, the P.D. is diminished to exactly the same extent as when air is used.

(5) If, on the other hand, *nitrogen* is sent against the crater, *no* diminution of the P.D. is observable.

(6) If air or oxygen is gently blown through the *negative* carbon, so that it cannot get direct to the crater, *no* diminution of the P.D. follows.

Thus there can be no shadow of doubt that *the sudden diminution of P.D. that accompanies the hissing of the open arc is due to the oxygen in the air getting directly at the crater and combining with the carbon at its surface.*

It only remains to show how the actual hissing *sound* may be produced by the burning of the surface of the crater. The moment this burning begins, a cloud of gas, formed of the products of combustion, must spread over the crater, protecting it momentarily from the action of the air as effectually as the carbon vapour had hitherto done. When this gas is dispersed, the air will again come in contact with the crater, a fresh cloud will form, and the whole action will start *de novo*. Thus a series of rushes and stoppages of the air will take place, setting up an irregular vibration of just the kind to cause a hissing noise. Not only this, however, but since the crater must cease to burn each time that it is protected by the gas, the diminution of P.D. must also cease to exist, since its cause is removed, and the P.D. will therefore rise momentarily. Thus an oscillation of the P.D. between the carbons, and, consequently, of the *electric* current, must be created, corresponding with the oscillation of the *air* current.

These oscillations of both air and electric currents do actually exist with the hissing arc. The first I have proved by means of a fine asbestos fibre fastened at one end to the hole in the crucible (Fig 8) through which the positive carbon moved. The asbestos ring was raised, and the space between the carbon and the crucible was left clear, and was made large enough to allow the free end of the short fibre to stretch out horizontally between the two. When the arc was silent, the fibre scarcely moved, but the moment hissing started it set up a vigorous vibration, instead of being sucked into the crucible as it would have been if there had been a steady inward current of air.

Messrs. Frith and Rodgers (*Phil. Mag.*, 1896, p. 420) showed, in 1896, that the *electric* current was oscillatory with the hissing arc, and Messrs. Duddell and Marchant (*Journ. Inst. Elec. Engs.*, vol. xxviii. p. 84) in the account of their beautiful experiments with the oscillograph, have given actual curves of the P.D. and current with the direct current hissing arc, showing distinctly the oscillations in both.

Thus the direct contact of the oxygen of the air with the crater of the positive carbon is capable of producing, not only the diminution of the P.D. between the carbons of the arc, which is the most striking accompaniment of hissing, but also every other important manifestation connected with it, including the sound itself.

HERTHA AYRTON.

## THE INTERNATIONAL CONFERENCE ON HYBRIDISATION AND CROSS-BREEDING.

IN this country where the application of biological principles to the industries which they underlie is left as a rule to private enterprise or the half-hearted interest of County Councils, any means whereby the scientific worker is shown to be useful to the practical man is a help towards a better state of things.

For this reason alone the Conference on Hybridisation suggested by Mr. W. Bateson, and held on July 11 and 12, under the auspices of the Royal Horticultural Society, may have more importance in the future than Prof. Henslow claimed for it in the present. The more immediate results that will accrue are those which the Society foresaw must arise if the attempt to call forth papers, remarks and exhibits dealing with hybridisation was at all successful. Two days were not many to devote to the meeting, and it is a matter of surprise that such an amount of work was done in the time. When, however, the whole of the contributions, whether read or unread at the conference, are published in the form of an illustrated report, the Royal Horticultural Society should be more than satisfied.

Nevertheless the question of hybridisation is so large, as Mr. Engleheart said in the discussion, that "whole sets of subjects" (graft hybrids, for instance) could not even be touched upon, and the suggestion made in several quarters, but by the American delegates in particular, that a supplementary conference be held in another country should be taken up seriously.

Before discussing the chief points of the meetings it may be of interest to give a list of the speakers and their subjects.

Tuesday, July 11, in the Society's Gardens at Chiswick:—

(1) Maxwell T. Masters, F.R.S., Introductory remarks as Chairman.

(2) W. Bateson, F.R.S., "Hybridisation and Cross breeding as a Method of Scientific Investigation."

(3) A. de la Devansaye, "Hybrid Anthuriums"

(4) Prof. Hugo de Vries, "Hybridisation as a means of Pangenetic Infection."

(5) The Rev. Prof. Henslow, "Hybridisation and its Failures."

(6) C. C. Hurst, "Experiments in Hybridisation and Cross-breeding."

Wednesday, July 12, at the Town Hall, Westminster.

(1) The Rev. Prof. Henslow, Introductory remarks as Chairman.

(2) Herbert J. Webber, "Work of the United States Department of Agriculture in Plant Hybridisation."

(3) Dr. J. H. Wilson, "The Structure of certain New Hybrids (*Passiflora*, *Albuca*, *Begonia*, &c.)"

(4) R. Allen, "Hybridisation viewed from the Standpoint of Systematic Botany."

(5) Henry de Vilmorin, "Hybrid Poppies."

(N.B.—Nos. 2 and 3 were illustrated by means of lantern slides, and No. 5 by large water-colour drawings.)

(6) Discussion; Prof. Henslow, Mr. Burbidge, Rev. G. H. Engleheart, Mr. George Paul, Mr. Bunyard, Dr. Masters, Mr. Willet Hays, and Mr. W. Cuthbertson.

The United States was represented by Mr. Herbert Webber, of the Department of Agriculture, his colleague Mr. Swingle, and Mr. Willet Hayes; France by MM. de la Devansaye

and Vilmorin; while among other "friends from across the sea" were hybridists from Germany, Holland and Switzerland.

With regard to the main body of our own countrymen who attended the conference, it must be said that horticulturists were very well represented, but that, with the exception of the readers of papers, biologists were few and far between.

Among papers of interest that were not read at the conference, but will appear in the report, the following may be mentioned:—

Prof. L. H. Bailey, "Progress of Hybridisation in the United States of America."
F. Morel, "Hybrids of *Clematis*."
P. Chappellier, "Essay on the Hybridisation of *Dioscorea*."
Émile Lemoine, "Hybrids of the Common and Laciniated Persian Lilacs."
L. Henry, "The Records of Hybridisation Experiments made at the Paris Natural History Museum between 1887 and 1899."
Charles T. Druery, "Fern Crossing and Hybridising."
Dr. Charles Stuart, "Hybrids of *Mimulus*, *Viola*, *Acquilegia*, &c."

During the first day's proceedings a fine show of hybrid plants and intergrafted genera was exhibited in the vinery at Chiswick.

Turning now to the material laid before the conference, it will be best to consider details under special headings.[1]

## I. THE QUESTION OF SPECIES.

*Significance of the Conception.*—As the word hybrid ordinarily means the result of a cross between two species, it follows almost necessarily that the question of what a species is was several times raised. Prof. Henslow was so bold as to give a definition, saying that "it is known by a collection of presumably constant characters taken from any or all parts of the plant."

It is necessary to have some idea for working purposes, but Dr. Masters came rather nearer to the mark when he said that the species once considered sacred, to-day practically represented the personal opinion of some man who had paid special attention to it.

Mr. Bateson again still clung to the opinion that species were often definite, but breeding work alone, he said, could throw light upon the subject. He contended that this had already shown that under the title of species and varieties "whole sets of (physiologically) distinct phenomena are confused together," and taking it as proved that species arise from discontinuous variations, he gave three instances where the same deviation from type was kept up discontinuously, but in three different ways:—

(*a*) The hairy wild form of *Matthiola incana* from the Isle of Wight was crossed with the smooth wallflower variety of the stock.
The offspring fell into two groups, and from the same capsule came one hairy and three smooth plants.

(*b*) The usual hirsute type of *Lychnis vespertina* and the hairless form cultivated by Prof. Hugo de Vries were bred together.
The offspring were all hairy, but on being left to fertilise each other, the second generation gave some hairy, some smooth individuals.

(*c*) The variations of *Biscutella laevigata* which occur in Switzerland, one with hairs and the other without (connected by but few intermediate forms), were lastly joined together.
The offspring were glabrous or intermediate in character, but as they became adult the latter forms lost all their hairs.

The experiments quoted are some made by Miss E. R. Saunders, of Newnham College, Cambridge.

*So-called Species sometimes Wild Hybrids.*—The fact that a number of so-called species occurring in nature have been reproduced by the crossing of other wild species was considered by Mr. Rolfe as of interest to systematic botanists, who must now recognise wild hybrids and the work of hybridists.

*So-called Species which are Garden Hybrids.*—During the discussion Mr. Burbidge showed what great confusion had arisen through the giving of Latin names to garden hybrids of whose origin no record had been kept. Matters would not be improved, one would fancy, through the practice of some nurserymen whom Dr. Masters alluded to in his address, and who, in the earlier days of hybridisation, imagined a foreign locality for their own productions in order to overcome the prejudice then prevalent against hybrids. Mr. Burbidge's suggestion was to give no classical names to hybrids; but if perforce the habit must be continued, let such parts of the parents' names be conjoined as would indicate the origin of the new form. In his paper M. Lemoine traces the previously obscure origin of a lilac by hybridisation experiments; while M. Henry suggests that the conference should undertake similar work, and mentions a number of plants to begin with whose garden history requires elucidation.

## II. THE LIMITS OF HYBRIDISATION AND CROSS-BREEDING.

*In general.*—Mr. Hurst gave statistics showing that up to date twenty-seven genera of Orchideæ, several belonging to different tribes as arranged by the systematic botanists, had been connected together by hybridisation. In other families so much has not been accomplished, but the same speaker noted five species of *Rhododendron* and four of *Gladiolus* that had been linked together. He said that the breeder might reasonably expect to be successful within the limits of a tribe; while, on the other hand, it was urged during the conference that an experiment is easy, and it is better to make it than to argue its non-success instead.

Dr. Wilson, in speaking of his results, said that he had hybrids of *Albuca*, in whose bodies five, if not more, original species were combined.

It can easily be seen that differences in structure may prove insurmountable barriers to hybridisation, but constitutional differences may often be disregarded. For instance, to quote Mr. Hurst, annuals can be crossed with perennials [M. de Vilmorin's poppies], deciduous trees with evergreens [Mr. Herbert Webber's oranges], plants from the tropics with plants from within the Arctic circle.

*Special Cases.*—Prof. Henslow discussed the question of some allied species which unaccountably will not cross, and he smilingly pointed out how much trouble would be saved if only one could tell plants' capabilities in the way of hybridisation from their outside appearance. Sometimes, he said, species of the same genus from different climates and habitats formed no hybrids, while even within the limits of a single species the red "geraniums" (*Pelargonium*) of France would not cross with English races; and certain strains of *Primula sinensis*, also mentioned by Mr. Hurst, and raised by Messrs. Sutton and Sons, were not fertile *inter se*.

*Non-reciprocity.*—Though many reciprocal crosses were recorded in the course of the conference, many failures, it was pointed out by the last-mentioned speaker, are known, but no further light was thrown upon the matter.

## III. CROSSING A MATTER OF CONDITIONS.

Some one alluded to the fact that, whereas it might be found impossible to effect a cross with the earlier produced flowers of an inflorescence, say, yet hybrids could be easily obtained from the blossoms that opened later. In connection with this, Dr. Wilson's hybrid *Passiflora* might be mentioned, where the first flowers to appear contained coronal rays, or else a second and miniature ovary within the walls of the usual one; but in the case of the flowers borne near the ends of branches the pistils were normal. The way in which it was again and again reported that a hybridising experiment had failed for one, two, three, up to seven years shows that successful crossing must depend in a great measure upon at present unknown conditions of nutrition, acclimatisation, temperature, or something else.

## IV. PREPOTENCY AND THE CHARACTER OF HYBRIDS.

*Non-prepotency of Sex.*—Where a hybrid appears to take after one parent in the more obvious and striking parts of its organisation it may resemble the other in more hidden but not less important characters (Mr. Hurst and M. Mael). Again, when species A, on being crossed with species B, produces hybrids that are practically replicas of itself ("false hybrids" of Millardet), it does not follow that the prepotent species, A, must necessarily be male or necessarily female (Henslow). Furthermore, reciprocal hybrids may be identical.

[1] For a *seriatim* account of the papers, see the *Gardeners' Chronicle*, series 3, xxvi. Nos. 655 and 656 (July 15 and 22).

*Partial Prepotency.*—This not very happy title is given by Mr. Hurst to a law which he puts forward as explaining, at least so far as the genus *Paphiopedilum* (= *Cypripedium*) goes, the varied results in the inheritance of characteristics. The law one takes to mean that in one part of an individual hybrid the mother, say, is seen to be prepotent; in another individual the same structure is inherited from the father: while in a third both parents are represented by an intermediate form of the special feature under consideration. We are then asked to imagine a real case where the combinations and permutations of all the component structures must be reckoned with. No doubt this brings the possibilities for variation very forcibly before us; but surely it is only giving another name to what must be expected whenever two parents representing two strains produce young. Although Prof. Ewart's zebra hybrids were mentioned by Mr. Hurst in another connection, yet little heed was given by any one to the possibilities of hybrid plants throwing back to ancestors in the dim past, as undoubtedly appears to be the case with animals.

*Prepotency of Varieties, Species, and Genera.*—Mr. Hurst's paper, which, indeed, was the only one that in any way systematically attacked the broad headings of hybridisation, contained much information deduced from the Orchideæ as to the inheritance by hybrids of the characters which are commonly valued as varietal, specific and generic. As might be imagined, the generic are most difficult to efface; the specific again are less lasting but more persistent than varietal, which are fleeting. Mr. Hurst had, however, to allow that distinct variations may transmit their qualities, and it would be difficult for him to do otherwise in the face of Mr. Bateson's examples; he gave exceptions, which he said are by no means rare—these come in when the variations are slight or the ancestry variable, and an abnormality he found to be transmitted either wholly or not at all. The case given by Prof. Hugo de Vries of the twisted variety of teasel (*Dipsacus sylvestris*) when crossed with *Dipsacus fullonum* being prepotent as regards the abnormality, exemplifies the former of these two alternatives. Prof. de Vries, it should be called to mind, explains it as a case of pangenetic infection. Finally, Mr. Hurst said that when the same variations are found in both strains, they may be traced in the second or following generations, but seldom otherwise. Prof. Vries' second experiment is at first opposed to this; but the latter stage confirms it. He desired to obtain artificially a hairless variety of *Lychnis diurna*, similar to one found in nature, and known as *L. presli*. To do this he crossed the ordinary hirsute variety with his glabrous form of *L. vespertina* already mentioned, and the hybrids were all uniformly hairy. The offspring of these again showed the characters of one or both parents in all degrees. Taking two glabrous examples and crossing them, a constant variety of *L. diurna* without hairs was forthwith obtained, starting with a batch of 390 plants, all glabrous.

*Parthenogenesis and Polyembryony.*—Prof. Henslow, among the many interesting details which he contributed, mentioned how pollen tubes are sent out even when the pollen of a pea is placed upon the stigma of a lily, and how on more nearly allied forms, although no fertilisation may take place, yet the irritation is enough to cause the empty ovary to swell and appear to contain seeds in a way comparable to the formation of galls (partial hybridisation). To explain cases where in crossing a species of one Orchid genus with others, *e.g. Epidendrum* with *Cattleya*, *Laelia* and *Sophronites*, the first was completely prepotent, Mr. Hurst advanced the theory that the occurrence was due to a kind of parthenogenesis, the pollen encouraging the egg-cells to develop into seeds without absolutely having the power to fertilise them.

A difficulty met with in the raising of hybrid races of oranges, which Mr. Webber described, is due to the fact that in the genus *Citrus*, adventitious embryos arise from the cells of the nucellus outside the embryo sac containing the normal egg. The result is that the latter only is affected by pollen, and from the seed arise several seedlings as shown in lantern pictures, only one of which can be the hybrid, the others reproducing the mother plant exactly.

*Vigour.*—The exceptional growth of hybrid plants being a well-known phenomenon was referred to again and again, and was put down by Mr. Hurst to the effect of out-crossing, as in-breeding he found in his experiments reduced the vigour at once.

*Diminution of Fertility.*—Dr. Wilson's results point to this being due to the poor development of pollen, and the lessened fertility of the male was shown by Mr. Hurst's statistics for *Paphiopedilum*. Of crosses in this genus between pure species 95·05 were successful: hybrids fertilised with pollen from pure species produced seeds in 91·82 per cent. of the cases; while pure species were only fertilised by the pollen from hybrids in 60 per cent. of the experiments. The case of male elephants being usually sterile in captivity seems worthy of mention in this connection. Mr. Hurst's generalisation that diminution of fertility is due to conditions of life rather than to any difference in the form or constitution of hybrids gains support, which is added to by the evidence given above under the headings II. (*Special cases*) and III.

*Microscopic Structure.*—Allusion was made to Dr. Macfarlane's work on the structure of primary hybrids, but what little was said about the microscopic conformation of secondary hybrids in *Albuca* (Dr. Wilson), and in *Rhododendron* (Prof. Henslow in the discussion), points to their possessing no internal characters of the importance of specific ones.

*Hybrid Races.*—That secondary hybrids differ more than primary ones from the parent species was the opinion of M. de la Devansaye and Mr. Hurst, and the latter speaker gave a series of figures showing the stability of the former kind; for out of 500 seedlings of a hybrid *Berberis*, 90 per cent. reproduced the immediate parent form, while in no instance was there complete reversion to either of the grandparent species. It is possible that many of our so-called wild species are stable hybrid races.

### V. THE ECONOMIC SIDE OF HYBRIDISATION.

Mr. Webber, in his remarks, and Prof. Bailey, in his paper, both told the same tale with regard to the United States. The bulk of the hybridisation on the other side of the Atlantic is carried on with a view to producing plants that will stand the particularly disadvantageous conditions of frost and drought, and so on, that occur in the wide tracts of land that must be cultivated, or to improving the yield or quality of special vegetable productions upon which many persons depend for their living. Ornamental hybrids are bought for the most part in Europe. The Government does a great part of the work of production, and the experiment stations carry out the work of testing new varieties, be they privately raised or otherwise, which at the same time allows the growers to see the value of the plants before they are distributed. Mr. Hays, in the discussion with regard to the little benefit accruing in this country to the raiser of a new plant, pointed out the opportunity given in America by the system just described for the said plant to be taken up. The Rev. G. H. Engleheart, as an amateur, and Mr. George Paul, as a nurseryman, talked of legislation whereby some sort of copyright should be established in new varieties. Mr. Bunyard pointed out objections, and showed how a man might raise sufficient stock before parting with any to ensure a profit he had calculated beforehand. This presupposes a fairly large sale, and might not be possible to the grower in a small way of business. Mr. Engleheart also alluded to there being no book in which the scattered facts so useful to the hybridist had been brought together.

Perhaps the time will come when there may be State authorities in this country to consider the scientific side of horticulture (as well as entomology and fisheries) in a modern way. At present the annual examination of the Royal Horticultural Society, upon the results of which certificates are granted, includes a theoretical test not only on the practical but on the scientific side. This certificate is the only recognised one which the gardener can obtain, and its value would be much enhanced if the examination were accompanied, or say followed, in the case of candidates who obtain a sufficient number of marks, by a practical examination in both branches of the subject

WILFRED MARK WEBB.

## UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

MR. W. A. HOUSTON, has been appointed to the post of assistant lecturer in mathematics in University College, Liverpool.

THE Agriculture and Technical Instruction (Ireland) Bill was read a third time in the House of Commons on Monday, and a first time in the House of Lords on Tuesday.

THE *University College School Magazine* announces that Mr. R. Tucker, who has guided the mathematical fortunes of the

school since 1865 with great success, will retire from his post at the close of this session.

DR. W. SOMERVILLE, professor of agriculture and forestry at the College of Science, Newcastle-upon-Tyne, in connection with the University of Durham, has been elected to the new professorship of agriculture in Cambridge University.

PARTICULARS concerning British, Continental and Canadian Universities, with special reference to institutions having courses open to women, are given in a "Handbook" compiled by Dr. Isabel Maddison for the Graduate Club of Bryn Mawr College, and published by the Macmillan Company, New York. We notice that Queen's College, London, which celebrated its jubilee last year, has been omitted. As the volume is primarily intended to indicate colleges for women students, the omission of a college of this kind possessing a Royal Charter is unfortunate.

THE departmental committee appointed by the Lord President of the Council to consider the question of the reorganisation of the Education and Science and Art Departments consists of Sir Horace Walpole, K.C.B (chairman), Sir G W. Kekewich, K.C.B., Secretary of the Education and Science and Art Departments, Captain W. de W. Abney, C.B., principal assistant-secretary of the Science and Art Department, Mr. S. Spring Rice, C.B., of the Treasury, and Mr. W. Tucker, C.B., principal assistant-secretary of the Education Department.

THE ninth summer meeting of University Extension Students will be opened at Oxford on July 29. Many prominent members of the University have arranged to take part in the meeting. In the scientific section Prof. Gotch will deal with "The Physiology of Sensation," Prof. Sollas will lecture on "The Geology of Oxford," Prof. H. A. Miers on "The Growth of a Crystal," Mr. H. N. Dickson, New College, on "The Influence of Climate," Mr. G. C. Bourne, University lecturer in Anatomy, on "The Growth of the Living Organism," Mr. G. J. Burch on "Wireless Telegraphy," and Dr. Arthur Ransome on "Microbes and Disease."

MR. A. F. STANLEY KENT has been appointed professor of physiology in University College, Bristol. Mr. Kent received his scientific training at Oxford, which he left upon being appointed demonstrator of physiology in Owens College, Manchester. In 1889 he was invited by Sir J. S. Burdon-Sanderson to take charge of the histological department at Oxford, to lecture on special points in physiology, and to assist in the teaching of general physiology. Since 1892 he has been assistant lecturer in physiology and histology at St. Thomas's Hospital, and has carried out a number of researches, the results of which have been published in various journals, proceedings, and reports.

SECONDARY as well as elementary schools are now beginning to appreciate the advantage of having upon their staff one or more teachers who thoroughly understand the application of the theory and practice of hygiene in school life; and the desirability of emphasising the necessity of this knowledge in the code for elementary schools is now being pressed upon the Education Department by memorials from several important bodies. To encourage the systematic study of the subject, the Council of the Sanitary Institute have decided to arrange a thorough theoretical and practical examination, which will be open to both classes of teachers and to those preparing as teachers. The first examinations will be held during February and June next year.

THE first of a series of articles dealing with the provision made by local authorities for the technical education of miners appears in the July number of the *Record* of Technical and Secondary Education, the information given having reference to the County Councils of Cornwall, Durham, Northumberland, and the West Riding of Yorkshire. The permanent schools of mining in Cornwall are at Camborne and Redruth, in the centre of the Cornish mining district, and they thus afford exceptional facilities for the acquisition of a practical as well as a theoretical knowledge of mining and its allied subjects. As regards the provision of practical work other than that concerned with elementary scientific principles, the Committee of the Redruth School have made arrangements with the managers of neighbouring mines for the practical instruction of the students. The Committee of the Camborne School adopt the same system to some extent, but are also themselves the owner of a portion of a mine, having purchased the same in 1897 for the use of students. Cornwall thus furnishes a unique instance of educational procedure by reason of this purchase of a mine by a local school committee.

As the result of a conference between representatives of the London School Board and London County Council, having for its object the prevention of overlapping of classes, the representatives of the former body have resolved to recommend the Board to adopt the following proposals among others:—(1) The School Board will limit its instruction in science and art in all its evening schools to such grades as can be conveniently taught in its premises, and will look to the Technical Education Board to give the advanced instruction in the premises under their control. (2) The School Board will not conduct classes in technological subjects, and will not offer instruction specially intended for university degrees. (3) The School Board proposes to conduct preparatory classes in elementary experimental science, in elementary freehand, geometrical, and model drawing, and in the drawing of simple pieces of mechanism; in mensuration and workshop arithmetic, and in algebra, to enable pupils to understand the meaning of an algebraical formula. (4) The School Board proposes to conduct evening classes in manual training, woodwork, and metal-work as part of a general education, and as preparatory to commercial workshops, but to refer students who are members of specific trades, and require trade teaching, to the Polytechnics and Technical Institutes.

## *SCIENTIFIC SERIALS.*

*Symons's Monthly Meteorological Magazine*, July.—Meteorological extremes: Pressure. Mr. Symons has undertaken to give, in alternate numbers, a list of extremes of the various meteorological elements. The task is by no means easy, as the information is scattered, in many books and languages, and some of the statements will no doubt lead to useful criticisms. The highest recorded barometric pressures (reduced and corrected) are 31·78 inches at Irkutsk, January 14, 1893; 31·72 inches at Semipalatinsk, December 16, 1877; and 31·62 inches at Barnaul, December 14, 1877. Dr. Woeikof doubts the accuracy of the first reading, *inter alia*, because the temperature for reducing *up* to the freezing point had been taken at $-51°·34$ F., and had been assumed to prevail from Irkutsk to the sea. He maintains that the reading of 31·62 inches at Barnaul is really the best established barometrical maximum as yet on record. The reduction to sea-level from stations some thousands of miles from the nearest sea renders the statements more doubtful than readings taken near the sea-shore. The highest readings in the British Isles are 31·108 inches at Ochtertyre, and 31·106 inches at Fort William, both on January 9, 1896. The highest reading in the neighbourhood of London since 1858 (the date of commencing observations at Camden Square) is 30·934, January 9, 1896. The lowest pressures are those referred to in NATURE, vol. xxxv. p. 344, viz. 27·135 on September 22, 1885, at False Point on the coast of Orissa. In the *Quarterly Journal* of the Royal Meteorological Society, vol. xiii. p. 212, Mr. C. Harding pointed out that for comparison with English standards a further subtractive correction of ·011 inch has to be applied, which would make the lowest reading 27·124 inches. The next lowest reading occurred at Ochtertyre on January 26, 1884, viz. 27·332 inches. The lowest reading at Camden Square is 28·295, December 9, 1896.

*Bulletin of the American Mathematical Society*, July.—The asymptotic lines of the Kummer surface, by Dr. J. I. Hutchinson, was read at the April meeting. These curves have been discussed by Klein and Lie, Reye, Segre and Rohn from the point of view of line geometry. This notelet gives a simple solution by making use of the parametric representation of the Kummer surface in terms of hyperelliptic functions.—On a definitive property of the covariant, by C. J. Keyser, was read at the same meeting. The writer refers to three proofs, due to Jordan, Elliott and Fiske respectively.—Yet another paper read at this meeting was the known finite simple groups, by Prof. L. E. Dickson. This is in part a *résumé* of previous work done by the author, and gives a table which should aid in the determination of the status of a newly-discovered simple group.—Reviews follow, viz. of Schoenflies' "Geometrie der Bewegung in Synthetischer Darstellung," and of Speckel's "La Géométrie du Mouvement Exposé: Synthétique," by Prof. F. Morley; a short notice of the second edition of the second volume of Weber's "Lehrbuch der Algebra," by Prof. Pierpont. Shorter notices

are Teixeira's "Corso de Analyse infinitesimal: Rudio's Verhandlungen der ersten internationalen Mathematiker-Kongresses in Zürich," vom 9 bis 11 August, 1897; Klein's lectures on the mathematical theory of the top; Moritz Cantor's "Politische Arithmetik oder die Arithmetik der taglichen Lebens"; and Virgilii and Garibaldi's "Introduzione alla Economia Matematica."—Prof. J. Pierpont gives a short note on elliptic functions, which discusses the simplest and most natural way of presenting the theory.—Notes, new publications as usual, and the index follow.

## *SOCIETIES AND ACADEMIES.*

### LONDON.

Royal Society, June 15.—"A Preliminary Note on the Morphology and Distribution of the Organism found in the Tsetse Fly Disease." By H. G. Plimmer and J. Rose Bradford, F.R.S., Professor Superintendent of the Brown Institution. (From the Laboratory of the Brown Institution.)

These observations are the result of an inquiry entrusted to us by the Tsetse Fly Committee of the Royal Society, at a meeting of the Committee on March 16, 1899.

The material for our investigations was obtained in the first place from a dog and a rat, inoculated with the blood of a dog suffering from the disease, by Mr. H. E. Durham, at Cambridge.

The organism found in the Tsetse Fly disease was discovered by Major Bruce, R.A.M.C., F.R.S., and was classed by him as a Trypanosoma. These belong to the order Flagellata, and, according to Bütschli, to the sub-group Monadina.

We will, in the first place, describe the adult form of the organism, such as is met with most frequently in the blood of a susceptible animal affected with the disease.

A. *Description of the Adult Form of the Trypanosoma.*

In freshly drawn blood examined as a hanging drop, or as a very thin layer in a cell, the adult form of the Trypanosoma can be easily studied. The latter method is the better, as the organism can be better seen and more accurately examined, in the thin, uniform layer of fluid than in the rounded drop. The easiest method of examining the blood in this way is to make, with a red-hot platinum loop and a small piece of paraffin, a thin ring of paraffin on an ordinary glass slide; the drop of blood is placed in the centre of the ring and a cover-glass placed on it, the thin layer of paraffin preventing pressure. If it be desired to keep the blood for continuous examination, it should be drawn into a graduated Pasteur pipette, and one-tenth part of a 5 per cent. solution of sodium citrate should be drawn up after it, then the blood and citrate solution should be carefully mixed in the bulb; the tube should then be sealed up, and drops can be taken from it as desired.

Under ordinary conditions of illumination the Trypanosoma, as seen in the blood, appears to consist of a uniform, homogeneous mass of protoplasm, of worm-like form, with at one end a thick, stiff extremity, and at the other a long, wavy flagellum. It is generally in active motion, and this is seen to be caused by the rapid lashing movement of the flagellum, and by the rapid contractions and relaxations of the mass of protoplasm forming the body, and by the movements of an undulating membrane which is attached to one surface of the body, and which appears to undulate synchronously with the contractions of the protoplasmic body. This membrane is, excepting at the free edge, very transparent, and can be seen much better in citrated blood which has been thickened by the addition of a small drop of 1 per cent. gelatine solution, when its contour and attachments can be much better made out, owing to the slower rate of vibration effected by the thickened medium.

The general shape of the Trypanosoma, when rendered quiescent by this means, but not killed, is that of a long oval, with one end blunt and the other continued into the flagellum; the membrane is then seen to be attached to one side of the body; it begins a little in front of the blunt end of the organism, and is continued at the end into the flagellum.

But with better illumination, such as a very oblique pencil of rays, or, better still, with monochromatic light (green or blue), the protoplasm is seen not to be homogeneous. The organism appears then as a highly refractive body, and near the middle, or between it and the flagellate end, is seen a large dark body much more refractive than the rest of the protoplasm; this is the macronucleus. Near the thick, stiff end of the body a tiny still more refractive body (with monochromatic light nearly black) is seen, which is the micronucleus. The addition of a drop of 5 per cent. acetic acid makes both of these bodies much more distinct. At the stiff end of the Trypanosoma, in varying relation to the micronucleus, is seen a vacuole. There is no suggestion of a mouth or of any organs, but the protoplasm with the most careful illumination appears not to be uniform, which suggests an alveolar structure, as described by Bütschli. With the ordinary simple stains (hæmatoxylin, fuchsin, methylene-blue, thionin) the differentiation is not much better than can be observed by careful illumination of living unstained organisms, as these stains are with these, and similar organisms, too diffuse to be of any service. Acting on a method which Ehrlich originated in 1889, and which Romanowsky modified in 1891, and which has still been further elaborated by Ziemann in 1898, we have used a mixture of methylene-blue and erythrosin, which has enabled us to follow the different stages of the Trypanosoma with certainty. This method depends on the fact that when a basic and an acid stain are mixed together in certain proportions, a third neutral body is formed, which has a specific colour reaction with chromatin. By the use of this method we have been able to trace the various stages of the organism in the blood and organs of the affected animals, which is not possible with the ordinary stains, these being useless for many of the forms to be presently described. With this method the macronucleus of the Trypanosoma is stained a clear, transparent, crimson lake, the micronucleus a deep red, and the protoplasm a delicate blue; these reactions are constant throughout all the stages of its life-history.

The protoplasm of the adult Trypanosoma does not stain uniformly, as does that of some of the other forms, but there are parts faintly stained and parts unstained, which is again in favour of the alveolar structure mentioned above. The vacuole is quite distinct as a clear round space when the organism is stained by this method.

The macronucleus is generally of an oval or elongated shape, and it may be either uniform in colour, or in the form of fine threads; this latter is seen especially in those forms which show other signs of division. The micronucleus is seen as an intensely stained round dot, or as a short rod, this latter form again being seen in those forms which show other signs of approaching division. With the highest powers (1·5 apochromatic objective and 18 compensating eyepiece of Zeiss) we have not been able to make out any special structural characters in this body. The flagellum is not stained by this method, but if the preparation has been well fixed, it is easily visible; the vibratile membrane also is unstained, and can be generally better studied in specimens stained by simple stains, preferably thionin.

As regards the movements of the organism, in preparations where no pressure is exercised, they can be seen moving either with the flagellum or with the blunt end in front; but we think that the commoner mode of progression is with the flagellum forward.

The size and length of the body varies very much with the period of the disease at which the blood is examined and with the kind of animal. The largest forms we have seen have been in rats' blood, just after death, and the smallest in rabbits' blood, early in the disease.

B. *Distribution of the Trypanosoma.*

(1) *In the Body of Normal Animals.*

(*a*) *In the Blood.*—We have found the flagellate form in the greatest numbers in the blood of the mouse, towards the end of the disease. In the rat also they occur in great numbers, and in both these animals they can be found in the blood on the fourth or fifth day. In the dog large numbers can be seen in the blood from the sixth day. In the cat they are fewer in number in the same lapse of time than in any of the animals before mentioned.

The rabbit seems to be the most refractory animal of any we have as yet used, and the Trypanosoma are found in the blood in small numbers only, and at very uncertain intervals.

(*b*) *In the Lymphatic Glands.*—In the superficial glands nearest to the point of inoculation the flagellate organism can be found earliest. In the rat the Trypanosoma can be found in the nearest superficial gland in twenty-four hours after inoculation. We have not found that generalisation of the organism in the lymphatic glands occurs until nearly the end of the disease, when the organism is present in very large numbers

in the blood. In the rabbit, in which the organisms are few or rare in the blood, the glands do not show any marked change, and the Trypanosoma are not readily found in them. Many other forms are found in the glands, to which reference will be made below.

(*c*) *In the Spleen.*—The adult Trypanosoma is found in but small numbers in the spleens of the various animals we have examined; but other forms are found there which will be described later. The enlargement of the spleen is *post mortem* the most obvious fact in the morbid anatomy of the disease; it may attain even to four or five times the average volume—this is especially the case in the rat.

(*d*) *In the Bone-marrow.*—We have found either very few flagellate organisms, or none at all, in the bone-marrow of the various animals we have worked with. The marrow is altered in colour and structure, but there does not seem to be a greater number of Trypanosoma than can be accounted for by the blood in the marrow.

In the other organs and parts, the number of organisms present depends upon the relative quantity of blood in the part.

(2) *In the Body of Spleenless Animals.*—As the spleen in the ordinary animals is the organ which is most obviously altered in this disease, we have made a series of inoculations into animals (dog, cat, and rabbit) from which the spleen had been removed a year ago. In the dog, the adult forms of the Trypanosoma are not found so early in the blood of spleenless as in that of ordinary animals (seventh day as compared with fourth day after inoculation). The glands, after death, are much more generally enlarged, and are reddish in colour, and contain many more organisms than in the normal animal. Both the blood and glands contain, however, numerous other forms to be described below.

This marked difference in the colour of the glands of spleenless animals is probably due to the removal of the spleen, and the glands consequently taking on some of the splenic functions.

The bone-marrow is much altered, and in it likewise are found a large number of Trypanosoma, both flagellate and what are termed below "amœboid" forms.

In the cat the conditions of experiment were altered, the blood (1 c.c.) from the infected animal being introduced, with every precaution to avoid contamination of the tissues, direct into the jugular vein. In this case the organism appeared in the blood in numbers on the fourth day, and the animal died on the twelfth day. As the Trypanosoma were introduced into the blood stream direct, there was no marked glandular enlargement, but the glands were all reddish in colour, the change in colour being due to the spleenectomy. A few adult organisms were found in the glands and in the bone-marrow.

In the spleenless rabbit a few Trypanosoma have been found in the blood on two occasions, but the animal lived nearly two months, and notwithstanding the failure to detect adult flagellate forms in the blood on numerous occasions, the blood was always infective, and contained numerous forms termed "amœboid" and "plasmodial" below.

### C. *Infectivity.*

(*a*) *In Ordinary Animals.*—The blood and organs of an animal dead of the disease lose, before twenty-four hours after death, their infective power. This is apparently due to the rapidity with which decomposition sets in after death, as we have found living Trypanosoma in film preparations, made as described above, as long as five to six days after removal of the blood from the body; and we have also found that large quantities (200 c.c.) of blood removed from the body into a sterile vessel and kept in an atmosphere of oxygen, retain their virulence for at least three days, notwithstanding the fact that the flagellate form cannot be demonstrated.

We have found that the blood of the dog is infective at least two days before any adult Trypanosoma can be seen in the blood; and we have also found that the blood of the spleenless rabbit, in which we have only on two occasions seen any adult forms, is invariably infective. This, of course, suggests the idea that the organisms must be present in another form, and we have been able, by the use of the method of staining described above, to demonstrate the presence of other forms in the blood and organs, and have shown, by the experiments just mentioned, that the infectivity of the blood, in cases where there are no flagellate forms discoverable, depends in all probability upon the presence of one of the other forms which the Trypanosoma assumes.

Although a differential staining method, such as the one we have used, is necessary for following and demonstrating the various stages of the life-history of the Trypanosoma, still these stages can be seen in unstained living specimens, with very careful illumination. As a matter of fact, our first observation of them was in unstained preparations.

In the blood of the dog, cat, rabbit, rat, and mouse, besides the adult forms as described above, which, as mentioned, are very various in size, there are adult forms undergoing division, both longitudinal and transverse, to which reference will be made later. Also two organisms are sometimes seen with their micronuclei in close apposition, or fused together, with more or less of their bodies also merged together. Such forms we believe are conjugations. Again, there are other large forms, with or without a flagellum, in which the chromatin of the macronucleus is broken up into a number of tiny granules, not bigger often than the micronucleus. Besides these there are other forms, which we call for convenience here "amœboid" forms, by which term we mean single, small, irregularly shaped forms, with or without a flagellum, but always with a macro- and micro-nucleus. These nuclear structures are generally surrounded by a very delicate envelope of protoplasm, of greater or lesser extent, but occasionally forms are seen which seem to consist only of chromatin, with or without a flagellum. Besides these, again, there are other forms which we call, also for convenience, "plasmodial" forms, meaning thereby an aggregation or fusion of two or more amœboid forms. In the blood these plasmodia are not generally very large, but may show evidence of from two to eight separate elements. Signs of division are very common; but in the blood one does not often meet with a plasmodium dividing up into more than four organisms of the adult shape. The plasmodial form also retains intact the two nuclear structures—the macro- and micro-nucleus—which we believe divide in the plasmodium, thus increasing its size.

In the spleenless animals the blood may contain no forms but the amœboid and plasmodial, such as is the case in the rabbit, yet this blood is infective; moreover, in the dog, before the adult organism appears in it, the blood is infective, and therein, at this period, these plasmodial forms can be demonstrated. In the glands these plasmodial forms are found, but only in quantity in those animals from which the spleen has been removed.

The spleen is the organ which shows these forms in the greatest abundance. The whole spleen is crammed in every part with plasmodia, which are wedged in between the splenic cells in every direction: many amœboid forms and also immature flagellate forms are also seen, but the most striking thing is the enormous quantity and uniform distribution of the plasmodia. The great enlargement of the spleen, which we have found constant in all the animals we have used, is caused by this mass of plasmodia, which we have found in the spleen within forty-eight hours from the time of inoculation.

In the marrow these plasmodial forms are only found, so far as our experience goes, in those animals from which the spleen has been removed. In these cases there are both plasmodial and amœboid forms in the marrow, the latter the more abundant.

The principal differences in the distribution of the plasmodial forms in animals with and without spleens is this: that in the animals with spleens the organ of choice for the plasmodia is the spleen, but they are also found constantly in the blood, and in less quantity in the glands, whereas in animals from which the spleen has been removed the plasmodial forms are plentiful in the blood, the glands, and the bone-marrow.

### D. *Life-History of the* Trypanosoma "Brucii."

Besides the forms mentioned above, we have seen in the blood and in the organs divisions of the adult form, both longitudinal and transverse, the former the more frequent; but we think that this direct mode of reproduction is far less common than the indirect by means of conjugation (probably), breaking up of chromatin, production of amœboid forms, with subsequent division of these amœboid forms, and the formation of plasmodia by the aggregation or fusion of the amœboid forms, and these finally giving off flagellate forms, at first small, and gradually increasing up to the normal adult form.

So that we should tentatively summarise the life-history of the Trypanosoma found in Tsetse Fly disease, which we think might properly be called "*Trypanosoma Brucii*," in recognition

of the work done in connection with it by its discoverer Major Bruce, F.R.S., as follows:—

(1) Reproduction by division, this being of two kinds:—

(*a*) Longitudinal, the commoner.
(*b*) Transverse, less frequent.

(2) Conjugation, consisting essentially, so far as our observations go, of fusion of the micro-nuclei of the conjugating organisms.

(*a*) After this we are inclined to place those forms mentioned above, in which the chromatin is broken up, and scattered more or less uniformly through the whole body of the Trypanosoma, since this occurs after conjugation in other organisms not far removed biologically from this one. The next stage in our opinion is the amœboid; we think that the flagellate form becomes amœboid perhaps after conjugation, but also probably apart from this process.

(*b*) Amœboid forms. These are found with and without flagella, of various shapes and sizes, but always possessing a macro- and micro-nucleus. These forms are constantly seen in the process of division, and sometimes are very irregular in shape, with, in this case, an unequal number of macro- and micro-nuclei, the latter being the more abundant. The amœboid forms then fuse, or aggregate, together to form—

(*c*) The plasmodial forms. Whether these are true plasmodia, or whether they are only aggregations of amœboid forms, it is not yet possible to say, but as many related organisms form true plasmodia we are inclined to look upon these masses, provisionally, as true plasmodia. In the spleen these plasmodia reach a large size. From these again are given off—

(*d*) Flagellate forms, which increase in size, and become the ordinary adult form. Small flagellate forms are not infrequently seen in process of separation from the margin of these plasmodial masses.

Besides these forms we have observed frequently, especially in rat's blood after death, the adult forms arranged in clumps. They appear, upon watching them for a considerable time, to get tangled together to form a large writhing mass; then the movements become gradually slower in the centre of the mass, and are only seen at the periphery. At this stage, if the specimen be fixed, the mass appears to be made up of a quantity of macro- and micro-nuclei, as the protoplasm does not stain, except in the organisms at the periphery, *i.e.* those which have arrived latest. Eventually these, too, become motionless, and the mass becomes an indistinct collection of granular matter, which is not infective, so that we look upon these tangles as a proof of death.

Since these observations were made, there has been published an important paper on the Rat Trypanosoma, by Lydia Rabinowitch and Walter Kempner in the *Zeitschrift für Hygiene*, vol. xxx. part 2. We have been able to confirm many of the observations and statements as to the morphology and reproduction of the Trypanosoma made by these writers. But there is no mention made of the plasmodial stage, or of any reproductive stage elsewhere than in the blood; and the writers recognise only three methods of reproduction, namely, longitudinal and transverse division, and division by segmentation. This segmentation, they consider, arises from *one* organism, and they state that it may divide up into as many as ten to sixteen elements. This segmentation form would seem to correspond to our plasmodial stage, but we have seen much larger masses than those mentioned above, and they do not notice the enormous masses of plasmodia which infiltrate the spleen in every direction, and which can be found also in glands and marrow. Moreover, their amœboid stage (Kugelform) would precede the segmentation form, and therefore the "Kugelform" should be much larger than the ordinary adult form, but we have observed that, as a rule, our amœboid forms are very much smaller than the adult forms, some not being visible with any but the highest magnifying powers; so that we have been unable to accept this form of division by segmentation, except in the form in which we have described it above, *i.e.* our plasmodial stage.

EDINBURGH.

Royal Society, July 3.—Prof. Copeland in the chair.—A telegram from Lord Kelvin was read on magnetism and molecular rotation. An electrified body is set into rotation by the generation of a magnetic field around it. The magneto-optic phenomena discovered by Faraday, Kerr, and Zeeman are to be thus explained.—Prof. Tait communicated a paper by Prof. C. N. Little on the non-alternate ± knots of the tenth order. The characteristic of non-alternate knots is that, as we pass round it, the crossings do not always come alternately above and below. The simplest non-alternate knot is one of eight crossings; and Prof. Little has now carried the census of these knots as far as the tenth order.—Prof. Sir W. Turner read a paper on contributions to the craniology of the people of the Empire of India: Part I. "The Hill Tribes of the North-east Frontier and the People of Burmah." Certain of the skulls which were shown, and discussed in detail, came from the Lushai-Chin region, and were, with few exceptions, of the dolichocephalic type. Yet the features of these people are distinctly Mongolian; and the typical Mongolian skull is brachycephalic. The same peculiarity was shown in eight skulls which Surgeon Lieut.-Colonel Wright had sent from the Naga Hills north of Manipur—the skull being dolichocephalic but the features Mongolian, and therefore usually belonging to the brachycephalic type. On the other hand, the Burmese skulls, which had been supplied by Surgeon Captain Bannerman and Surgeon Major Bell, were, with two exceptions, brachycephalic.—Sir William Turner also read a paper on decorated and sculptured skulls from New Guinea. These had all come from British territory. The sculptured skulls were of special interest, the sculpturing in all cases being executed on the frontal bone. Sir William distinguished five distinct types of sculpturing, and threw out various speculations as to their significance.—Dr. Hepburn described and exhibited an improved form of craniometer for the segmentation of the transverse, vertical, and antero-posterior diameters of the cranium. In this improved form of cranial calliper, the graduated bar has zero at its centre, and the two curved legs of the callipers are both movable, each along its own half of the bar, which is graduated from the centre outwards. At the centre of the bar a straight calliper leg is introduced, being sunk in an undercut groove so that it may be adjusted to any required convenient length. The instrument may be used as an ordinary calliper by removing the centre limb, clamping the one calliper leg, and reading on the reverse side of the bar, which is graduated continuously from end to end. In using the improved form, we place the point of the central limb on any desired spot, and adjust the two curved limbs until they touch the ends of the chord to be measured. The measurements give, not only the length of chord, but also indicate the amount of asymmetry. The instrument had been tested on a number of skulls of various human races and of anthropoid apes. The relative heights of cerebrum and cerebellum had been determined, the position of the occipital condyles in relation to the greatest length had been studied, and a variety of other results obtained. In all such measurements the dolichocephalic skulls came nearer to those of the anthropoid apes than the brachycephalic skulls.—Mr. J. Y. Buchanan read a paper on the meteorology of Ben Nevis in clear and in foggy weather. The days in which the mountain was enveloped in cloud were first separated from the days when a clear atmosphere prevailed, the minimum of foggy weather being taken as three consecutive days, and the minimum of clear weather as twenty-four consecutive hours. As was to be expected, the foggy weather contained all the worst weather, and the clear weather all the best. Also in foggy weather the barometer was, on an average, half an inch lower than in clear weather.

July 10.—Prof. Copeland in the chair.—At the request of the Council, Prof. Cargill G. Knott gave an address on earthquakes, their propagation through the earth, and their bearing on the question of the earth's internal state. A brief sketch of the history of earthquake research was followed by an account, illustrated by lantern slides, of the various forms of seismographs, seismoscopes, seismometers, tromometers, &c., which have been devised, more especially in Italy and Japan, for the recording of the gentler types of earthquakes, and of seismic vibrations too feeble to be perceived by our senses. This led to a discussion of the main characteristic of those minute vibrations which have their origin at an earthquake focus, and pass across thousands of miles to be recorded on suitable instruments at localities not themselves subject to even feeble shocks. The results recently established by Prof. John Milne, F.R.S. (see various letters in last volume of NATURE), were then described, and certain conclusions deduced. The manner in which a far-travelled earthquake disturbance was drawn out in time seemed to be better explained in terms of a

solid than of a fluid earth. Reasons were also given for believing that seismic activity was greater in earlier geologic times than now; and that, if this were so, stratigraphical changes would almost certainly have taken place more quickly in former ages.

PARIS.

Academy of Sciences, July 17.—M. van Tieghem in the chair.—On the combinations of sulphide of carbon with hydrogen and nitrogen, by M. Berthelot. A mixture of hydrogen and carbon bisulphide was submitted to the action of the silent discharge for some hours. The carbon bisulphide was found to have combined with about half its volume of hydrogen. Similar experiments with nitrogen in place of hydrogen showed that combination also took place, the proportions in two experiments being $7CS_2 : N_2$ and $4CS_2 : N_2$.—Remarks on the combination of nitrogen with oxygen, by M. Berthelot. The author's results agree with those obtained by previous workers in the same field.—On the advantages of autumn crops, and their usefulness as a green manure, by M. P. Deherain. A green crop, such as vetch or potato, sown over the wheat stubble immediately after the harvest, is usually successful if the months of August and September are not too dry.—Remarks by M. Lœwy on some lunar photographs presented by M. Weineck.—On some transformations of some right lines, by M. E. O. Lovett.—On the general theory of congruences of circles and spheres, by M. C. Guichard.—On the Mossotti-Clausuis and Betti formulæ relating to the polarisation of dielectrics, by M. F. Beaulard. The author investigates a formula for the dielectric capacity of a mixture of a conductor and a non-conductor, and shows experimentally that for a mixture of copper and paraffin the formulæ of Poisson and of Betti both agree with the results found.—Do rarefied gases possess electrolytic conductivity? by M. E. Bouty. From the experiments quoted the author concludes that the electrical properties of a gas cannot be considered as resembling those of any known electrolyte. For a given pressure of gas there is a certain value for the strength of field below which the rarefied gas acts as a perfect dielectric. As the strength of the field is increased there is produced a sudden change, manifested by the luminescence of the tube.—On the reversible temporary and residual variations in nickel steels, by M. C. E. Guillaume.—On chromic acetate, by M. A. Recoura. Chromium acetate, $Cr(C_2H_3O_2)_3$, has been obtained in four isomeric forms; thus differing from the other chromium salts previously studied, which only give two.—On the prevention and cure of toxic epilepsy by the injection of normal nerve substance, by MM. V. Babes and Bacoucea. Injections of nerve substance were found in some cases to retard or prevent epilepsy artificially induced in rabbits.—On the presence of a soluble reducing ferment in the animal organism. Reducing power of extracts of organs, by MM. E. Abelous and E. Gerard. The kidney of the horse, macerated with chloroform water, gives a ferment capable of reducing potassium and ammonium nitrates to nitrites. It decolorises methylene blue, and appears to give butyric aldehyde with butyric acid. The ferment is destroyed at 72° by mercuric chloride solution, but the activity of reduction is not impaired by the addition of such antiseptics as thymol or sodium fluoride.—On the development of the chicken, by M. Etienne Rabaud.—Tarsian regeneration, and regeneration of the members of the two anterior pairs in the leaping Orthoptera, by M. Edmond Bordage. The loss of the front pair of appendages is usually fatal to the insect, but when it survives, if still in the larval state, regeneration may give a perfect member again. The contradiction to the law of Lessona is only apparent.—Division of the nucleus in the spermatogenesis of man, by M. Sappin-Trouffy. The two modes of division studied yielded multiplication cells with a single nucleus, and polynucleated reduction cells, or mother cells of spermatozoids.—Osseous regeneration, followed with radiography, by M. Abel Buguet.—Radiography of calculus of the kidney, by MM. Albarran and Contremoulin. The exact position of the renal calculi was discovered by radiography previous to removal.—Radiography of the heart and aorta at the different phases of cardiac revolution, by M. H. Guilleminot.—The *rôle* of the locomotor organs in the horse, by M. P. Le Hello.—On the development and pisciculture of the turbot, by M. A. Eugène Malard. The culture of the turbot would appear to be easy provided the basins are of sufficient capacity.—Experimental researches on dreams. On the continuity of dreams during sleep, by M. Vaschide.

AMSTERDAM.

Royal Academy of Sciences, June 24.—Prof. H. G. van de Sande Bakhuyzen in the chair.—Prof. Schoute reported, on behalf of Prof. Cardinaal and himself, on the treatise by Mrs. Alicia Boole Stott, entitled "On certain series of sections of the regular four-dimensional hypersolids" The conclusion of the report, viz. that the treatise should be inserted in the *Transactions* of the Academy, was approved.—Prof. Lobry de Bruyn made, on behalf of both Dr. A. Steger and himself, a communication concerning the influence of water upon the rapidity of the formation of ether from methyl iodide and ethyl iodide, and from sodium methylate and sodium ethylate. This inquiry, which is a sequel to a previous study of the conversion of *o*-dinitrobenzol with sodium methylate and sodium ethylate, showed that the addition of constantly increasing quantities of water did not prevent the occurrence of constant reaction coefficients. In the case of methyl iodide it was possible to continue the inquiry down to pure water; as in the case of the above-mentioned reaction with *o*-dinitrobenzol, water here also proved to cause the reaction coefficient in ethyl alcohol to constantly decrease, while in the case of methyl alcohol it first rose and then also fell. That the sodium, dissolved in aqueous ethyl alcohol of 50 per cent., was for the greater part present as alcoholate, was proved by an experiment the result of which was that ethyl iodide was for the greater part converted into ordinary ether by such a solution.—Prof. Bakhuis Roozeboom made two communications: (*a*) on an instance of conversion of mixture crystals in a compound; (*b*) (on behalf of Dr. Ernst Cohen and Mr. C. van Eyk) on the enantiotropy of tin.—The following papers were presented for publication in the *Proceedings*: (*a*) one by Prof. J. C. Kluyver, on the continuation of a univalent function represented by a doubly infinite series; (*b*) one by Prof. Kamerlingh Onnes, on standard gasmanometers; (*c*) one by Mr. N. Quint (presented by Prof. Van der Waals), on determinations of the isotherms of mixtures of hydrochloric acid and ethane; and one by Prof. Lorentz (also presented by Prof. Van der Waals), on the elementary theory of Zeeman's effect, being a reply to the objections of Prof. Poincaré.—Prof. Mulder presented for publication in the *Transactions* a treatise entitled "On peroxy-silver sulphate and peroxy-silver acetate" (sixth paper).—Prof. H. G. van de Sande Bakhuyzen communicated the fact that the comet the orbit of which was computed a few years ago by Mr. Zwiers in a treatise published by the Academy had appeared again, and that the place observed corresponded very closely with the one computed beforehand.

## NORWEGIAN MARINE INVESTIGATIONS.

*Bergens Museum. Report on Norwegian Marine Investigations*, 1895–97. By Dr. Johan Hjort, O. Nordgaard and H. H. Gran. (Bergen: John Grieg, 1899.)

THIS Report contains two papers, the first, on the "Currents and Pelagic Life in the Northern Ocean," by Drs. Hjort and Gran, and the second, "A Contribution to the Study of Hydrography and Biology on the Coast of Norway," by O. Nordgaard.

In the first paper, the authors give the general results of their observations on the hydrography and pelagic life of the Northern Ocean obtained during recent years. More detailed results of their observations in Norwegian waters, with especial reference to the herring fishery, are reserved for future publication.

It may at once be said that this work, though only an instalment, is a very important contribution to oceanographical knowledge, and well sustains the character of Scandinavian research.

The first chapter deals with the hydrographical condition of the Northern Ocean, and the second chapter contains plankton studies in the same region. Then follow voluminous and detailed tables of the actual observations. These tables are illustrated by a series of seven plates, which show easily and very clearly the peculiarities of the region under description.

The Northern Ocean, as a deep-water basin, lies on the polar side of a curved line passing through Iceland, the Farö Islands, and reaching the Norwegian coast at the point where its trend changes from north to north-east. The shallow water portion includes all the Norwegian littoral waters and the portion of the North Sea between Norway and Scotland lying north of latitude 57° or 58° N. The Wyville Thomson ridge connecting Iceland with the Farös and the Orkney Islands is debatable ground separating the Atlantic from the Arctic areas. The position and the bathymetric characteristics of the different regions are very well shown in Plate I., taken from Mohn's "Northern Ocean."

Along the entire Norwegian seaboard there are three deep regions of well-marked hydrographic characters: (1) The region of periodical changes to a depth of 200 or 250 metres; (2) the Atlantic region to a depth of 500 metres; and (3) the Arctic region. Referring to this classification, the authors say:

"Of these regions it is chiefly the uppermost that is of interest to us, as it is our main purpose to unravel all the conditions which may influence the migration of fishes; and it may well be presumed that the great changes produced by currents, by summer warmth and winter cold, and the variations from year to year of the different factors, may be of the greatest importance to the periodical fisheries."

In pursuing the investigations of these conditions, five sections of the sea off the coast between Stavanger and Lofoten were made in 1895 by Hjort, and the same ground was gone over by Nordgaard in the winter of 1896. The results of these investigations are shown graphically in Plates VI. and VII. The figures in these plates take the form of sections running out from the Norwegian coast to a depth not exceeding 400 metres, and showing the distribution of depth, temperature and salinity. Of these, the most interesting are those made in the same locality in summer and in winter. The difference of season affects principally the water at and near the surface, and is dependent on the rainfall in Norway. If the west coast of Norway were a perpendicular cliff, and the whole of the rain which falls on it ran eastwards, the fluctuation of conditions with which this paper deals would be either non-existent or insignificant. The physical observations of the papers are mainly directed to chronicling the variations in the salinity of the coast waters, and especially in the quantity of water of low salinity, which has a tendency to cover the surface and monopolise the summer heat received from the sun, of which it contributes next to none to the layers immediately below it. This view, that the freshening of the coastal waters, with all its consequences, is due to the mixture of Atlantic water with fresh water from the continent, and not to the addition of water from the Arctic ocean, is developed in considerable detail in the paper. In so far the paper is of a polemical and, indeed, of a more or less national character, because the opposing view is especially identified with Sweden, and the one supported by the authors with Norway. It is, however, a form of polemic from which nothing but profit is likely to result to science. With regard to the evidence afforded by plankton studies, which have been held to favour the Arctic theory, the authors say in their *résumé*:—

"As all inflowing bodies of oceanic water are of an Atlantic kind, the Arctic organisms, which may be met with at certain times, must in any case pass through Atlantic water if they really are derived from the Arctic currents, but their subsequent appearance in the colder and fresher waters on the coast is no proof of the coastal water's Arctic origin."

The concluding paper by Nordgaard, dealing mainly with the food of the cod, is very interesting, but not of a kind to be easily abstracted. In presenting the results of his investigations, he makes some important remarks. He admits that the fluctuations of the herring fishery are largely, though not exclusively, due to changes in the physical conditions of the sea in the spawning regions.

Referring to the cod, he says:—

"We are thus led to the conclusion that a principal factor in the produce of the Lofoten fisheries is the number of the fish that migrate inwards, and as the migration from the ocean, according to the observations hitherto made goes on in such a great depth that the annual variations in the physical conditions are very insignificant, we are obliged to look for another explanation of the change, in the numbers of the immigrations. I am apt to think that much can be derived from changes in the numbers of the fish staying on the outer banks. In the same way in which we speak, for instance, of a bad grouse season, by which we mean that the number of grouse is small, we may certainly also speak of a bad cod season."

It will be seen that this, as well as the preceding papers, are of a very detailed character, and they well repay careful study.

J. Y. B.

## PROJECTIVE GEOMETRY.

*Premiers Principes de Géométrie Moderne.* Par E. Duporcq. Pp. viii + 160. (Paris: Gauthier-Villars, 1899.)

It is a curious fact that while projective geometry is becoming better appreciated in England it seems to be going out of favour in France. M. Duporcq, in his introduction, pathetically deplores the predominant place assigned to analysis in the syllabuses of the official examinations; and in France, as with ourselves, most teachers are compelled to neglect a subject that does not pay. It will be sad indeed if, in the fatherland of Monge, Poncelet and Chasles, pure geometry is to be deposed from her former high estate, and made a kind of Cinderella, called in to do odd jobs for Her Serene Highness the Princess *Analyse*, or to amuse the children with tricks of the triangle.

M. Duporcq's book itself helps us to realise the danger that is threatened. One cannot help feeling that his attitude is apologetic, and that his exposition is a half-hearted one. At the very outset we are confronted with homogeneous coordinates; homography is based on an algebraic relation; points at infinity lie in a plane "by definition"; imaginary elements have no real existence, and the introduction of them, due to analysis, is a mere *façon de parler*, vaguely justified by the "Principle of Continuity." With all respect to Poncelet, it may be doubted whether his "principle of continuity," apart from algebraical considerations, has any real working value; on the other hand, von Staudt elaborated, forty years ago, a theory of imaginary elements which, so far as curves and surfaces of the second order are concerned, gives a consistent geometrical theory (quite independent of analysis) in which the principle of continuity has a real meaning, and is at the same time practically self-evident, as one would expect it to be. Von Staudt's name does not appear to be mentioned in M. Duporcq's book, and the reader might not unreasonably infer that the author was ignorant of v. Staudt's existence.

It would, of course, be absurd to advocate the exclusive use of pure, as opposed to analytical, geometry, even in problems of a strictly geometrical character. The ideal geometrician should be equally expert in both methods, and apply one or the other or both combined according as circumstances may require. But it may fairly be urged that a treatise on the *first principles* of projective geometry should avoid the introduction of coordinates except by way of illustration, and for the purpose of showing the points of contact between the two methods. It is right to teach an apprentice the use of a saw as well as that of a plane; but you will not attain this end by giving him a tool that is neither a saw nor a plane, but contains something of both.

Thus to give an explicit example, M. Duporcq frequently infers homography from a one-to-one relation established, not from an equation, but from the inspection of a figure. Thus (p. 49):

"Si donc $m$ et $m'$ désignent les deux points où une droite quelconque $\Delta$ coupe une conique circonscrite au quadrangle $a\,b\,c\,d$, on voit qu'à tout point $m$ de $\Delta$ ne correspond ainsi qu'un point $m'$. Comme, d'ailleurs, ces points sont évidemment réciproques, ils déterminent donc une involution sur $\Delta$," &c.

These statements are doubtless correct, but are they sufficiently justified? How is the beginner to distinguish the argument from the following:

"Two points S, H are taken on a tangent to an ellipse, and any ellipse with foci S, H cuts the given ellipse in the points M, M′: then to each point M corresponds one point M′ and *vice versâ*, hence we have a system in involution, and MM′ goes through a fixed point"?

It is not a sufficient answer to say that M, M′ are only a pair of four associated points, because this is not geometrically evident. Again, we have cases of Cremona correspondence with the fixed points imaginary: how is the untrained student to distinguish them from homographic correspondences?

We are far from wishing to suggest that M. Duporcq's work is devoid of interest and value. Considering its size it is remarkable for the range and variety of its contents; it comprises a very attractive and, indeed, brilliant sketch of homography, poles and polars, involution, quadratic transformation (including inversion), together with an outline of Lie's line-sphere correspondence. For a reader prepared by previous study, it affords an excellent and suggestive *résumé;* it is rather when it is examined as a methodical text-book for students that it seems to us to fall short of perfection. To the student we would still say: Read Reye, work his exercises, and then, if you like the subject, gird up your loins and tackle von Staudt. For it is a truth past gainsaying that v. Staudt's "Geometrie der Lage" and the immortal "Beiträge" contain, as no other books do, the essentials of projective geometry.

G. B. M.

## A SYSTEM OF PHYSICS.

*Kanon der Physik.* By Felix Auerbach. Pp. xii + 522. (Leipzig: Viet and Co., 1899.)

SCIENTIFIC books may be divided into two groups, those which are written because the author has something to teach, and those which are written because he has something to learn. It is no reproach to a writer if his book is classed with the second group, for there may be as much originality in learning as in teaching, and his autodidactic efforts will often prove a source of instruction to others. It is not possible to say whether Prof. Auerbach has been consciously writing his "Kanon" of physics to clear up his own ideas on scientific principles, but the book he has produced gives the impression that this has been one of his principal motives; and I would even go a step further and say that, if life were long enough, every physicist ought, when he gets to the age of fifty, to spend three years in putting his ideas into shape and write a similar treatise. It would serve as a kind of "Abiturienten Examen" to his state of crystallisation.

It is easier to talk about this book in vague and general terms than to give an account of what it is and what it contains. I am afraid of becoming definite in my own words, for fear of giving a wrong impression, and must content myself with the translation of a few sentences taken out of the preface.

"A comprehensive book is still wanting—and not only in Germany—in which the conceptions, principles,

theorems and formulæ, dimensional relations and numbers belonging to physics are represented and put together in a systematic manner, and in a way which would do justice to two different intentions: to give on the one hand to the reader a general view of the whole, without disturbing him by methodical, historical and other details, and on the other hand to give without circumlocution, to any one who may consult the book, a definite answer to his questions. The great difficulty in principle of such a 'Kanon' of physics lies clearly in the fact that it is in exact science often, perhaps generally, impossible to give a short answer to a short question. If a scientific man is asked, What is mass? What is elasticity? What is entropy? he takes a long breath and begins with a long introduction—and not without reason; for the difficulty of a short and detached answer lies in the nature of the thing. But we must not consider the difficulty to be insurmountable. We must fix our mind on what is essential and characteristic, and give expression to it in our answer; as for the rest, so far as is necessary, it may be added afterwards by supplementary remarks."

The volume which the author has produced to satisfy his requirements is worth reading because it is stimulating. Irritating would perhaps be the better word for the principal sensation felt in perusing it, because we constantly come across statements which do not seem to coincide with our own views, or with explanations which do not satisfy; yet in spite of trying hard, it is difficult sometimes to point out what it is that does not satisfy, and even if one succeeds one feels that the thought one has been obliged to give to the matter has cleared and perhaps modified one's own views. The book begins with a number of chapters on general principles, space, time, motion, force and mass and the properties of matter. The subject is treated in a concise, short and instructive manner, but the author does not always succeed in giving us, as promised in the above passage, a short answer to a short question. His definition of dispersion, *e.g.*, takes up eight lines and wants reading eight times before it can be understood. After a short chapter in which the principal equations of the potential theory are put together and explained, the author enters into the two chief divisions of the book, "energy" and "entropy." He takes a rather wide and unusual view of the latter word, including under it all transformations of energy. Without entering into the difficult question of classification, we may commend these two chapters, which most physicists will read with profit. But surely a better definition of electric current might be given than the one on p. 250:—

"When one observes, that the potential has different values at different points of a conductor, one expresses this fact also by saying: a certain quantity of electricity moves in the conductor, or an electric current flows in it."

The difference of potential at different points is by no means characteristic of an electric current, as for instance in air, where we are constantly dealing with such differences. Dr. Auerbach, to make his explanation correct, must therefore lay stress on a sharp distinction between conductors and non-conductors; but how would he define a conductor except by arguing in a circle, and saying that a body is a conductor when a fall of potential causes an electric current.

Among the points of the book which are irritating without being stimulating, we may mention the very annoying method of numbering concurrently and independently his paragraphs, according as they contain matters of principle or laws and propositions. Thus § 52, printed in fat type, follows § 158 printed in somewhat leaner characters, and whenever a reference has to be looked up, one has to investigate the type carefully, and if it is, *e.g.*, 91 fat, turn to p. 385; while if it is 91 lean, find the required passage on p. 118. We hope that in future editions a different system will be adopted.

Lecturers will find one use, perhaps not a very high one, for this book; it will save them thought and labour, by helping them to arrange their course in a systematic and orderly fashion. ARTHUR SCHUSTER.

## OUR BOOK SHELF.

*Insects: their Structure and Life. A Primer of Entomology.* By George H. Carpenter, B.Sc. (Lond.). Pp. xi + 404. (London: J. M. Dent and Co., 1899.)

MR. CARPENTER, Assistant Naturalist in the Science and Art Museum in Dublin, is favourably known to entomologists by numerous valuable papers on *Lepidoptera*, *Odonata*, cave-insects, economic entomology, &c.; and we are very pleased to welcome a useful introductory manual of entomology from his pen. It is compiled from a variety of sources, special use having been made, in the chapters on the form and life-history of insects, of the well-known work on the cockroach by Profs. Miall and Denny. These chapters will be found very useful, especially as the names attached to the various parts of insects are clearly and carefully explained. Classification and the principal orders and families of insects are then dealt with as fully as the space at the author's disposal would allow; and chapters on insects and their surroundings and on the pedigree of insects close the body of the book, which concludes with a short bibliography and a good index. Perhaps Chapter v., on insects and their surroundings, will be found most interesting to the general reader; for it treats of such subjects as cave-insects, fresh-water insects, marine insects, geographical distribution, mimicry, &c. Mr. Carpenter usually expresses himself very cautiously, but when he says that the number of described species of insects amounts to a quarter of a million, and that there are probably two millions of species still undescribed, we are inclined to think that both his estimates are very much below the mark. The number of described species of insects cannot be less than 300,000 at present, and many entomologists think that the late Prof. Riley's estimate of the number of existing species of insects as ten millions is by no means to be regarded as extravagant. Mr. Carpenter's remarks on the various subjects connected with evolution are very well expressed and reasoned out. W. F. K.

*Year-book of the United States Department of Agriculture*, 1898. Pp. 768. (Washington: Government Printing Office, 1899.)

THE volume before us, like so many of its predecessors which have been noticed in these columns, is full of contributions of interest and value to students of science, agriculturists and others. Although appealing primarily to residents in the States, many useful hints and suggestions may be gleaned from the year-book by its readers in this country. The report of the Secretary of the Department shows that the varied operations carried on have been prosecuted with vigour. The Department has at present four scientific explorers abroad getting seeds and plants—one in Russia, one in the countries

in the neighbourhood of the Mediterranean, one in the China Seas, and one in South America. It is stated in connection with the forestry division that 100,000 acres are under forestry experimentation. The State Agricultural Experiment Stations report an active year, about 400 reports and bulletins having been issued during the year to over half a million addresses. As is fitting at the present time, the volume contains special articles on the resources of Puerto Rico and the Hawaiian Islands.

*Organoterapia.* By Dr. E. Rebuschini. Pp. viii + 442. (Milan: Ulrico Hoepli, 1899.)

IN the introduction Dr. Rebuschini briefly deals with the history and general nature of organotherapy. The main substance of the book is devoted to a detailed account of the glandular secretions and other substances derivable from the several organs of the animal body, and the applications of these fluids to the treatment of disease. As the author points out, the most successful branch of organotherapy up to the present time has been that of the thyroids, and this alone occupies nearly half of the book.

## LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

### Undercurrents.

IN NATURE for July 13, p. 261, is given an abstract of a paper lately read by Admiral Makaroff, of the Imperial Russian Navy, before the Royal Society of Edinburgh, on the subject of double currents, *i.e.* of currents in reverse directions in different strata of water in certain straits. Admiral Makaroff gives his opinion on the causes of these reverse currents, and as they are diametrically opposed to those that I hold, I think that it may not be uninteresting to give my reasons for differing from him.

Admiral Makaroff considers that difference of density of the water is the primary and, indeed I gather he thinks, the only cause of these opposing currents; but he brings no evidence beyond theoretical considerations in support of his belief.

Let us consider his instance of the Bosporus.

In 1872, as Admiral Makaroff very kindly mentions, I made a series of observations on the undercurrents in this Strait and in the Dardanelles,[1] and showed that when the surface water, of a very low specific gravity, was flowing from the Black Sea to the Mediterranean, the water in the lower strata of the Straits, of a high specific gravity, was running strong in the opposite direction.

But the surface current does not always flow in this direction. It is sometimes almost still, and on occasions the movement is towards the Black Sea. The lower strata respond, and are either also still, or move in the opposite direction.

It is evident that as the Mediterranean water is always of a high specific gravity, and the Black Sea surface water always of a low specific gravity, if the difference between them is the primary cause of the opposing currents the latter would always flow in the same direction, and that as they do not in fact behave in this manner, there must be some other force at work.

My observations soon led me to conclude that this force is the wind.

The prevailing wind in the summer and autumn, in which I made my observations, is from the N.E. When it blew from this direction, the surface current ran towards the Mediterranean. When it was calm the water was in the Dardanelles, ordinarily, still, and in the Bosporus often so. When the wind came from the westward, the currents were reversed.

I do not know how the deduction from these facts can be got over. I am quite ready to admit that the difference in specific gravity will cause a slow circulation in the direction in which the two currents ordinarily run, but in the face of their undoubted reversal under the circumstances which I have related, it appears to me that there can only be one conclusion.

It was on the ground that the direction of the wind is the prevailing factor that I believed that we should find a similar condition of affairs in the Strait of Bab-el-Mandeb, and as I stated in a communication to NATURE, vol. lviii. p. 544, these conditions were, by observations most ably carried out by Commander Gedge, R.N., in H.M.S. *Stork* in 1898, proved to exist.

There are here none of the differences of specific gravity demanded by Admiral Makaroff's hypothesis, and I consider that the existence of the reverse undercurrent in Bab-el-Mandeb, when the north-east monsoon is forcing the water on the surface into the Red Sea, absolutely proves the correctness of the theory that wind is the primary cause of this interesting circulation. Admiral Makaroff in his paper merely mentions the Strait of Bab-el-Mandeb as a place where the double-currents occur, but says nothing about them; and I am not aware that any observations but those made by H.M.S. *Stork* have been carried out in this Strait.

Admiral Makaroff is a close and indefatigable observer, and oceanography owes him much, but I cannot help thinking that in this instance his enthusiasm for densities has led him away. However, I shall be glad to hear reasons to the contrary, as I only desire the truth.

W. J. L. WHARTON.

Florys, Wimbledon Park, July 25.

[1] Report on the Currents of the Bosporous and Dardanelles. (Hydrographic Office. Potter, London.)

### The Duties of Provincial Professors.

SINCE the appearance of the article "The Duties of Provincial Professors" in NATURE, I have daily been wishing to write to thank you for it, but hitherto have been hindered partly by want of a convenient opportunity, and partly by the feeling that all the points brought forward are so absolutely accurate, and the article is so complete, that it leaves nothing further to be said. The warning it contains as to the danger of making true culture subservient to competition is most timely. I have an experience of many years as an officer in a provincial university college, and know, to my cost, how rank is the growth of the spirit of competition with rival colleges, and how widespreading are its roots. And this is at the sacrifice of the best intellects and ability of the colleges. It results usually in the resignation of the most original and brilliant characters who may have sufficient private means to secure a bare independence; while the others remain quite at the mercy of their governing body, who may at any moment—even without any assigned motive—give them notice to resign. This and the very inadequate salaries attached result in constant changes in the staff. Further, the fever of competition induces the different university colleges to take up technical and pedagogical training, adding department after department at a rate greatly in advance of their means, so that no side can be worked to its full development owing to an insufficient staff and an overburdened exchequer.

A question which has frequently arisen in my mind of late is, Are we to allow without protest a different standard of morals to our governing bodies from that accorded to individuals?

In *bulk* their income is derived from public sources; why should councils of university colleges, whose existence depends upon such sources of income, be allowed the power to close their meetings to reporters? Are they to be allowed freedom of method without danger of exposure? Must we quietly allow them to fix the salaries of their officers at their own pleasure at an average which is much below the market value of the services rendered—in some cases even so low as 50 per cent. below the average rate? Is this honest? No: *it is thieving the best energies of some of our most able minds!*

Those of their officers who lack private means know that they dare not speak the thoughts of their hearts. They hardly dare protest, or courteously ask—even in the most considerate manner, for colleges have their known difficulties—for their legitimate due, for they know very well that, until they have another post to step into, they are helpless.

These things ought not to exist. They are a slow poison sapping the life of true education, rendering systems which are almost ideal in theory of no account in practice.

July 25. VERITAS.

## PHOTOGRAPHIC RESEARCHES ON PHOSPHORESCENT SPECTRA:

### ON VICTORIUM, A NEW ELEMENT ASSOCIATED WITH YTTRIUM.[1]

IT has long been known that certain substances enclosed in a vacuous glass bulb phosphoresce brightly when submitted to molecular bombardment from the negative pole of an induction coil. The ruby, emerald, diamond, alumina, yttria, samaria and a large class of earthy oxides and sulphides emit light under these circumstances. Examined in a spectroscope the light from some of these bodies gives an almost continuous spectrum, while that from others, such as alumina, yttria and samaria, gives spectra of more or less sharp bands and lines. Since 1879 I have been working on these phosphorescent spectra, chiefly in connection with the earths of the yttria group, and by chemical fractionation I have succeeded in separating from this group bodies whose phosphorescent spectra consist chiefly of single groups of lines, other groups being absent. For the last six years the research has been extended beyond the visible spectrum, and photographs of the ultra-violet portion of the spectra are now being taken with a spectrograph with a complete quartz train. Some of the results of this investigation were exhibited at the soirée of the Royal Society on May 3. A preliminary mention of the discovery of a new element was made in my address to the British Association in September last, when I provisionally called it Monium; but for several reasons I now consider the name Victorium more appropriate.

The complicated scheme of fractionation carried on for so many years is illustrated in the accompanying diagram. This must be considered only as an indication of the methods employed, and not as an actual representation of every operation through which the material has passed. Crude yttria, from samarskite, gadolinite, cerite and other similar minerals, is the raw material. The first operation is to free it roughly from earths of the cerium group—an operation effected by taking advantage of the fact that the double sulphates of potassium and the yttrium metals are easily soluble in saturated potassium sulphate solution, while the corresponding double sulphates of the cerium group of metals are difficultly soluble.

After this preliminary treatment, the crude yttria is converted into nitrate, represented by the topmost circle on the diagram. The nitrate is exposed to heat until it fuses to a clear liquid, care being taken to distribute the heat uniformly through the mass. Presently the liquid mass commences to decompose, giving off red vapours. After this has proceeded for a little time, the fused mass is carefully poured into water, and the liquid well boiled. A white precipitate of basic nitrate forms, while the undecomposed nitrates remain in solution. These are separated by filtration—the precipitate going to the right and the solution to the left. The basic nitrate is dissolved in nitric acid, and the right and left solutions are then evaporated to dryness and fused as before. Partial decomposition by heat again divides each of these portions into two lots, soluble and insoluble. The soluble from the left-hand lot goes still further to the left, and its insoluble portion to the right. The soluble from the right-hand portion goes to the left, where it mixes with the insoluble from the other portion, while its insoluble portion goes still further to the right. This series of operations is continued for as long a time as the material will hold out.[2] From a description, the process seems to be more complicated than it really is, but a study of the diagram and the direction of the arrows makes it clear. The number of times this operation is performed varies with each lot of earth fractionated. The portions submitted to fusion rapidly diminish in quantity, and the

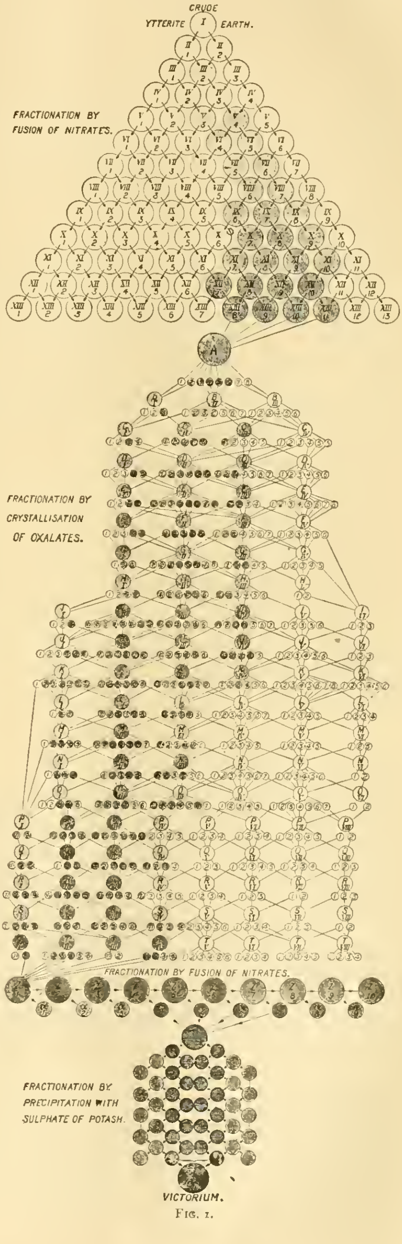

FIG. 1.

[1] A paper read before the Royal Society, May 4, by Sir William Crookes, F.R.S.

[2] "On the Methods of Chemical Fractionation," British Association, Birmingham Meeting, 1886; *Chemical News*, vol. liv. p. 131.

operation is continued until the material becomes too scanty.

The last horizontal line of fractions, spectroscopically examined in a radiant matter tube, shows differences in the visible spectrum. For many years I recorded these differences in coloured drawings, which have served on several occasions to illustrate papers before this Society.[1] In the year 1893 I commenced to record the differences between the various spectra by photographing them in a spectrograph having a complete quartz train, and since that time attention has chiefly been directed to the variations in the number, character and positions of the lines and bands in the ultra-violet spectrum; these are more striking than those which are visible, and as they are self-recording, results are more rapidly attained. A description of this instrument is given further on.

On placing the photographed spectra of one of the horizontal lines of earths in order, several differences are detected. One striking difference is seen in the behaviour of a group of lines in the ultra-violet. It is nearly absent in the end fractions, gradually becoming stronger towards the middle, and attaining a maximum in the fractions situate about two-thirds towards the right. This shows that at least three different bodies are present: one, the great bulk, having a nitrate difficult to decompose; another, whose nitrate is easiest to decompose; and a third body, occupying an intermediate position, whose nitrate decomposition occurs at temperatures between that required by the others, but nearer that of the nitrate easiest decomposed.

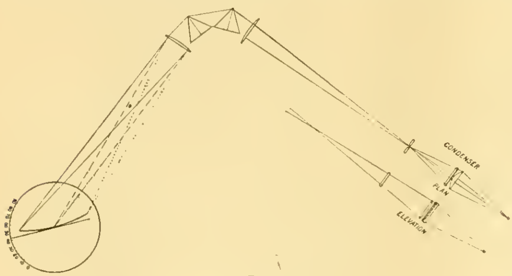

FIG. 2.

The above method of fractionation is not so effectual if more than two bodies are present. In that case the process fails, in any reasonable time, to yield practically pure specimens of more than two out of a group of closely allied earths. Thus, if there are three earths—say A, B and C—whose positions in reference to the chemical process employed are in the written order of sequence, we may get a specimen of A as nearly as we please free from B and C, and a specimen of C as nearly as we please free from A and B, but we cannot get a specimen of B practically free from A and C. The law seems to be that to obtain practically pure specimens of three closely allied earths, it is essential to have recourse to at least two different chemical processes. The mere continued repetition of the same process will not do, unless, indeed, the operations are repeated such a vast number of times as to make the approximate expressions no longer applicable, even though the substances are chemically very close.

For this and other reasons it is advisable to change the method of fractionation after one process has been in operation for some time. It is evident that any process of fusion, crystallisation or precipitation can only divide the mass of material into two parts, a soluble and an insoluble portion, crystals and mother liquor; and after a time a balance of affinities seems to be established, and further fractionation appears to do little good. It is better then to change the operation.

Following the diagrammatic scheme, the portions of earths containing most victorium are collected together and fractionated by the crystallisation of the oxalates from a solution strongly acidulated with nitric acid in the following manner:—

To a boiling acid solution of the nitrate a small quantity of hot solution of oxalic acid is added. The solution remains clear, and it is only after vigorous stirring that a small quantity of insoluble oxalate is formed. The whole is thrown on a hot-water filter and slightly washed with boiling water. To the boiling filtrate a fresh lot of hot solution of oxalic acid is added, and stirred till more insoluble oxalate comes down. This is again filtered off, and the operations of precipitating, stirring, filtering, and washing are repeated, always keeping the temperature as near the boiling point as possible, until the whole of the earths are precipitated. Generally the initial earth is divided by this method of fractionation into from six to twelve portions. Each of these oxalates is dried, ignited, dissolved in nitric acid, and the above-described operations repeated. Photo-spectroscopic tests are constantly taken during the progress of this fractionation, and portions are mixed together according to the data thus obtained, as shown on the diagram by the lines joining the fractions. The object being to avoid lateral spreading as much as possible, and, while concentrating the special line-giving earth, to prevent its too great diffusion over a large number of fractions. When the fractionation by the oxalate method has proceeded for a considerable time, the fractions rich in victorium are collected together and submitted to another mode of treatment.

These fractions are converted into nitrates, and a small quantity is thrown out by partial decomposition by heat, according to the method already described. The filtrate is evaporated to dryness and again fused, so as to throw out a little more. This operation is repeated as long as any soluble nitrate is left. Generally from six to twelve portions are thus obtained. These form a regular series, differing according to the stability of the nitrate under heat. On testing, the victorium is found to concentrate in the centre portions, being less easily decomposed than the earths of the cerium group, and more easily decomposed than those of the yttrium group.

The fractions rich in victorium are converted into sulphates and mixed with a hot saturated solution of potassium sulphate. The precipitate is dissolved in boiling water and mixed with a further quantity of solution of potassium sulphate. This produces a small quantity of a precipitate. The filtrate from the first precipitate is also mixed with fresh potassium sulphate, and the operations are repeated, mixing the centre solutions to one lot and the side solutions to another, as shown by the lines on the diagram. It is found on photo-spectroscopic examination that the earths thrown out on each side are poorest in victorium, whilst those in the middle are richest. After a time no further concentration is effected in this manner, all the earths that can be removed as being more or less soluble in potassium sulphate having been eliminated.

In thus describing the method of fractionation, my object has been not so much to give a description of the plan actually carried out in the laboratory—for the details have varied with each operation—but to give an intelligible idea of the general manner in which a very complicated operation is effected. In the diagram I am supposing that one particular substance, victorium, is to

[1] "On some New Elements in Gadolinite and Samarskite Detected Spectroscopically" (*Roy. Soc. Proc.*, No. 245, 1886 vol. xl. p. 502).

be separated, and I have endeavoured to show its migrations and gradual concentration as the work progresses, by tinting the fractions where it mostly would concentrate, the depth of tint representing the amount of concentration.

In the purest condition yet obtained victoria is an earth of a pale brown colour, easily soluble in acids. It is less basic than yttria and more basic than most of the earths of the terbia group. In chemical characters it differs in many respects from yttria. From a hot nitric acid solution victorium oxalate precipitates before yttrium oxalate and after terbium oxalate. On fractional precipitation with potassium sulphate the double sulphate of victorium and potassium is seen to be less soluble than the corresponding yttrium salt, and more soluble than the double sulphates of potassium and the terbium and cerium groups. Victorium nitrate is a little more easily decomposed by heat than yttrium nitrate, but the difference is not sufficient to make this reaction a good means of separating victorium and yttrium. Fusing the nitrates can, however, be employed advantageously to separate mixed victoria and yttria from the bulk of their associated earths.

On the assumption that the oxide has the composition $Vc_2O_3$, the atomic weight of victorium is apparently not far from 117.

The photographed phosphorescence spectrum of victoria consists of a pair of strong lines at about $\lambda$ 3120 and 3117; other fainter lines are at 3219, 3064, and 3060. Frequently the pair at 3120 and 3117 merge into one, but occasionally I have seen them quite distinct. The presence or absence of other earths has much influence on the sharpness of lines in phosphorescent spectra, and it is probable that these lines will be sharp and distinct when victoria is obtained quite free from its associates.

The best material for phosphorescing in the radiant matter tube is not the earth itself, but the anhydrous sulphate formed by heating the earth with strong sulphuric acid and driving off the excess of acid at a red heat. The sulphate thus produced, probably also containing some basic sulphate, is powdered and introduced into a bulb tube furnished with a quartz window, and a pair of thick aluminium poles sealed into the glass with stout platinum wires. The tube is well exhausted, keeping the current from a good induction coil going all the time. The pumping and sparking must continue until the earth glows with a pure light free from haze or cloudiness, and continues so to glow during the passage of the current without deterioration. The exposure in the spectrograph usually occupies an hour.

I give a diagrammatic plan of the two-prism spectrograph used in this research. It is furnished with two quartz prisms, quartz lenses and condensers. The slit jaws are of quartz, cut and polished according to the method I described in the *Chemical News*, vol. lxxi. p. 175, April 11, 1895.

The prisms are made in two halves according to Cornu's plan, one half of each being right-handed and the other half left-handed. One of the lenses also is right-handed and the other left-handed. By this device the effect of double refraction is so completely neutralised that with a five-prism instrument it is impossible, under high magnifying power, to detect any duplication of the lines.

The lenses are each of 52 mm. diameter and 350 mm. focus. The focus of the least refrangible rays is longer than that of the most refrangible rays, and the sensitive film must therefore be set at an angle to get the extreme rays into focus at the same time. But this alone is not sufficient. The focal plane is not a flat surface, but is curved, and the film must therefore be curved,[1] and it is only when both these conditions are fulfilled that perfectly sharp images of spectral lines extending from the red to the high zinc line 2138·30 can be photographed on the same surface. Celluloid films are used, glass not being sufficiently flexible.

Using the middle position showing the whole spectrum on a plate, the angle is 40°, and the curvature is 190 mm. radius.

The condensers are of quartz, and are plano-cylindrical — one being double the focus of the other. The object of this, when spark-spectra are being photographed, is to concentrate on the slit a line instead of a point of light, as would be the case if ordinary lenses were used.

When photographing phosphorescent spectra—or, in fact, any spectra the wave-lengths of which are either unknown or require verification—I always photograph on the same film a standard spectrum, usually of an alloy of equal molecular weights of zinc, cadmium, tin and mercury. This forms a hard, somewhat malleable alloy, giving throughout the whole photographic region lines the wave-lengths of which are well known. The chief objection to this alloy is its volatility, the poles requiring frequent adjustment. Recently I have used pure iron for this purpose; this has the advantages of giving a great number of fine lines whose wave-lengths are accurately known, and not being very volatile, the poles do not rapidly wear away. If the poles are kept about 1 mm. apart, there is little or no interference from air lines.

The most simple method of applying the standard lines to an unknown spectrum is by the successive employment of two slightly overlapping diaphragms immediately behind the slit, one being used for the experimental and the other for the standard spectrum. In this way, without disturbing the instrument, the two spectra can be recorded on the plate one over the other; the overlap of 1 mm. being in the optical centre of the train. The resulting negative is then transferred to a micrometer measuring machine of special construction, having a screw of 1/100th of an inch pitch, and a means of accurately determining 1/1000th of its revolution, thus measuring directly to the 1/100000th of an inch. In this way, in a five-prism spectrograph having lenses 700 mm. focus, it is possible to determine wave-lengths of photographed lines to the sixth figure.

## *MATHEMATICS OF THE SPINNING-TOP.*[1]

### I.

"TO those who study the progress of exact science, the common spinning-top is a symbol of the labours and the perplexities of men who had successfully threaded the mazes of the planetary motions. The mathematicians of the last century, searching through nature for problems worthy of their analysis, found in the toy of their youth ample occupation for their highest mathematical powers.

"No illustration of astronomical precession can be devised more perfect than that presented by a properly balanced top, but yet the motion of rotation has intricacies far exceeding those of the theory of precession.

"Accordingly we find Euler and D'Alembert devoting their talent and their patience to the establishment of the laws of the rotation of solid bodies. Lagrange has incorporated his own analysis of the problem with his general treatment of mechanics; and since his time Poinsot has brought the subject under the power of a more searching analysis than that of the calculus, in which ideas take the place of symbols, and intelligible propositions supersede equations" (Maxwell—"Collected Works," I. p. 248).

Newton also cites the top as affording an experimental verification of his First Law of Motion—Lex. I. ". . .

[1] "Ueber die Theorie des Kreisels." F. Klein und A. Sommerfeld. Heft i, ii. Pp. 196 and 197 to 512. (Leipzig: Teubner, 1897–8.)

Trochus, cujus partes cohaerendo perpetuo retrahunt sese a motibus rectilineis, non cessat rotari, nisi quatenus ab aere retardatur." We can translate *trochus* as a top, as well as a wheel or hoop.

But Newton lived too early to calculate any quantitative explanation of the theory of the top, and even his attempt at the simpler problem of precession was not a very great success. (Principia, lib. III., Prop. xxxix.) We had to wait for D'Alembert to straighten out the difficulties of first principles before arriving at an exact solution.

The key-note of the present treatise is found in § 2—"Analytische Darstellung der Drehungen um einen festen Punkt"—and in the bilinear relation in equation (5) on p. 25,

$$(1) \qquad \lambda = \frac{\alpha\Lambda + \beta}{\gamma\Lambda + \delta}, \text{ with } \alpha\delta - \beta\gamma = 1,$$

expressing analytically the displacement of a rigid body about a fixed point.

If $x, y, z$ are the coordinates of a point with respect to axes fixed in space, and X, Y, Z of the same point with respect to axes fixed in the body,

$$(2) \qquad \lambda = \frac{x + yi}{r - z} = \frac{r - z}{-x + yi},$$

while $\Lambda$ is the same function of X, Y, Z; thus $\lambda$ and $\Lambda$ play the part of a stereographic representation of the point on the sphere of radius $r$ with respect to the poles in which the sphere is intersected by the axes O$z$ and OZ.

Expressed by Euler's unsymmetrical angles $\theta, \phi, \psi$,

$$(3) \qquad \alpha = \cos\tfrac{1}{2}\theta e^{\frac{1}{2}(\phi+\psi)i}, \qquad \beta = i \sin\tfrac{1}{2}\theta e^{-\frac{1}{2}(\phi-\psi)i}$$

$$\gamma = i \sin\tfrac{1}{2}\theta e^{\frac{1}{2}(\phi-\psi)i}, \qquad \delta = \cos\tfrac{1}{2}\theta e^{-\frac{1}{2}(\phi+\psi)i},$$

satisfying

$$\alpha\delta = \cos^2\tfrac{1}{2}\theta, \qquad \beta\gamma = -\sin^2\tfrac{1}{2}\theta,$$

and

$$\alpha\delta - \beta\gamma = 1.$$

By putting

$$(4) \qquad \alpha = D + Ci, \qquad \beta = -B + Ai,$$
$$\gamma = B + Ai, \qquad \delta = D - Ci,$$

so that

$$A^2 + B^2 + C^2 + D^2 = 1,$$

the versor-quaternion

$$(5) \qquad Q = Ai + Bj + Ck + D$$

is obtained, which determines the displacement; this gives the authors an opportunity for an excursion into the Quaternion-Theory so far as required in their subject, and should delight the soul of Prof. Tait, always anxious to see more frequent applications of his favourite subject, to which allusion is made on p. 509.

In Maxwell's opinion, it is the introduction of the ideas, as distinguished from the operations and methods of Quaternions, which is valuable; and now we have McAulay's "Octonions" to assist, with plentiful illustrations of the dynamics of our subject.

The important use of the above bilinear relation between $\lambda$ and $\Lambda$, for the treatment of the motion of a rotating body or a top, was pointed out by Prof. Klein in a lecture at Göttingen University in the winter-semester of 1895; the further development of the formulas was chosen by Prof. Klein as the subject of his Princeton Lectures in October 1896; and the present work is intended to be a complete presentation, with the collaboration of Prof. Sommerfeld.

Subsequent historical research, described on p. 511, has shown that the germs of similar ideas can be traced back through Hess (p. 429), Weierstrass (p. 511), up to Gauss in 1819. Gauss appears at the same time to have had some prophetic inspirations of the Quaternionic Theory, but as usual he carefully bottled up his ideas. It was said of the works of Friar Roger Bacon in the middle ages—"partim mutili direptis hinc inde quaternionibus facti, tam raro comparent, ut facilius sit Sibyllae folia colligere quam nomina librorum quos scripsit"—and the same might be said of Gauss's unpublished manuscripts, now at length to be edited completely by the Göttingen Academy of Sciences, under the direction of Prof. Klein, the present occupant of Gauss's chair. We think then that Prof. Klein is too generous in renouncing the priority of his discovery, considering that he was the first to make the invention really work, and that his precursors allowed the germs of the idea to pass from them unfertilised, not perceiving their real importance.

In the special case of the symmetrical top the functions $\alpha, \beta, \gamma, \delta$ can be expressed by elliptic-theta functions; Prof. Klein calls them "multiplicative elliptic functions"; their form is given explicitly on p. 520, and now the solution is complete from the point of view of the mere mathematician of the school of—"Shut your eyes and write down equations."

"Mais il faut convenir que, dans toutes ces solutions on ne voit guère que des calculs, sans aucune image nette de la rotation du corps."

The authors, giving heed to this warning of Poinsot, devote the rest of the book to a careful examination and classification of the various cases which may occur; and also to what the ordinary mathematician in general so cordially detests, the working out and drawing in a diagram of some well-chosen numerical cases; only in this way is it possible to make sure of the accuracy and reality of the abstract formulas, and to lift mathematical science out of the arid collection of analytical results.

A first great requirement for the study of the movement of the top is an actual model, as shown on p. 1, or else a top such as that devised by Maxwell ("Collected Works," I. p. 248); sufficient rotation can be imparted by twirling the spindle by the finger; and a slight blow with the hand will give any desired variety to the pattern of the curve described by the end of the axle. A bicycle wheel, spinning in its ball bearings, supported in a fixed cup, would also serve the purpose.

As we have three independent constants at our disposal with the top, the number of possible cases is threefold infinite ($\infty^3$); and so the choice of a numerical case is at first sight an embarrassing one in its variety.

In the book the constants employed are such that (p. 223)

$$(6) \qquad t = \int \frac{du}{\sqrt{U}}, \quad u = \cos\theta,$$

$$(7) \qquad \psi = \int \frac{n - Nu}{A(1-u^2)} \frac{du}{\sqrt{U}}$$

$$(8) \qquad \phi = \int \frac{N - nu}{A(1-u^2)} \frac{du}{\sqrt{U}} + N\left(\frac{1}{C} - \frac{1}{A}\right)t$$

$$(9) \qquad A^2U = (1-u^2)(k - N^2 - 2APu) - (n - Nu)^2$$
$$= (1-u^2)(k - n^2 - 2APu) - (N - nu)^2.$$

Here we must make the criticism that until p. 299 the mechanical interpretation of the quantities P, $n$, N is not very clearly defined so as to have their numerical values assigned in the C.G.S. system of units. Given the top we are to experiment with, we must first weigh it; denote the weight by W grammes; next measure the distance, $h$ cm., between the C.G. and the point of support; then W$gh$, dyne-cm., is the static moment denoted here by P, $g$ denoting the acceleration of gravity (981) in cm./s.$^2$. The number A denotes, as usual, the moment of inertia, in g.cm.$^2$, of the top about an axis through its point perpendicular to its axis of figure; A can be determined experimentally by swinging the top as a plane or conical pendulum, and measuring the length of the equivalent pendulum, $l$ cm., and the angular velocity $m$ when swung without rotation as a conical pendulum of small aperture; then

$$l=\frac{A}{Wh}, \quad A=Whl=\frac{Pl}{g},$$

and

$$m^2=\frac{g}{l}=\frac{Wgh}{A}=\frac{P}{A}.$$

So also C denotes, as usual, the moment of inertia, in g.cm.$^2$, about the axis of figure, and, with an angular velocity $r$ rad./sec. about the axis of figure, $N = Cr$, the angular momentum about the axis; while $n$ is the constant angular momentum round the vertical $Oz$.

In the discussion of the numerical cases, the authors start by taking a root $u = e$ of the cubic $U = 0$ as given, and then examining the various relations which subsist between N and $n$. But if one root of the cubic is known, the other two are determined by the solution of a quadratic, so that we may take all these roots as the three data of the question, and follow Darboux's method, as explained in the notes to Despeyrous' "Cours de Mécanique."

We may, for symmetry with Weirstrass' notation, denote the two extreme limits of $\theta$ by $\theta_2$ and $\theta_3$, so that $\cos\theta_2$ and $\cos\theta_3$ are two roots of the cubic U; the third root, being greater than unity, may be denoted by $\operatorname{ch}\theta_1$, and now

$$A^2U=2AP(\operatorname{ch}\theta_1-\cos\theta)(\cos\theta_2-\cos\theta)(\cos\theta-\cos\theta_3)$$
$$=2APV$$

suppose, with

$$\operatorname{ch}\theta_1>\cos\theta_2>\cos\theta>\cos\theta_3.$$

It is not clear how any simplicity is gained by considering negative as well as positive values of P (p. 248); this seems to introduce needless complication in the classification, as we can take P always positive, and measure the angles $\theta_2$ and $\theta_3$ from the upright vertical position of the top. There may be a slight disadvantage in the case of the spherical pendulum, in which the chief part of the motion takes place in the lower hemisphere, but the counterbalancing advantages of simplicity of classification prevail on the whole.

In Darboux's representation of the motion of the axis by means of the generating lines of a deformable hyperboloid, we take a focal ellipse, of which the ratio of the axes is equal to the modulus $\kappa$ of the real period; the comodulus $\kappa'$ of the imaginary period $\omega'$ is thus the eccentricity of the focal ellipse; and

(10) $$\kappa^2=\frac{\cos\theta_2-\cos\theta_3}{\operatorname{ch}\theta_1-\cos\theta}, \quad \kappa'^2=\frac{\operatorname{ch}\theta_1-\cos\theta_2}{\operatorname{ch}\theta_1-\cos\theta_3}.$$

The two generating lines HP and HP′ are placed in position at an angle $\theta_3$ as tangents to the focal ellipse, and the deformable hyperboloid is completed in Henrici's manner by a number of other rods as tangent lines, knotted together at the points of crossing. With this model we can represent graphically the various constants of the problem.

Returning to the case considered by the authors, where $\theta_3$, N, and $n$ are given, we can select an arbitrary length OD, and measure off lengths HQ, HQ′ along two straight lines inclined at an angle $\theta_3$, such that

(11) $$\frac{HQ}{OD}=\frac{n}{2\sqrt{AP}}, \quad \frac{HQ'}{OD}=\frac{N}{2\sqrt{AP}};$$

and draw the perpendicular QO, Q′O to the lines meeting in O. We are now given the conjugate semi-diameters OH and OD, by which the ellipse can be described through H, and the confocal ellipse, touching HQ and HQ′, is the focal ellipse of the deformable hyperboloid.

On this diagram

(12) $$\cos\theta_3=\frac{OH^2-AB^2}{OD^2}, \quad \sin\theta_3=2\frac{OS\cdot OM}{OD^2},$$

$$\cos\theta_2=\frac{OH^2-OS^2}{OD^2}, \quad \sin\theta_2=2\frac{OS\cdot ON}{OD^2},$$

$$\operatorname{ch}\theta_1=\frac{OH^2+OS^2}{OD^2}, \quad \operatorname{sh}\theta_1=2\frac{OQ\cdot HP}{OD^2};$$

$$\frac{k}{2AP}=\frac{3OH^2-AB^2}{OD^2}=\operatorname{ch}\theta_1+\cos\theta_2+\cos\theta_3.$$

If $\theta_1$, $\theta_2$, $\theta_3$ are given, then

$$e^{\theta_1}=\frac{HS'}{HS}, \text{ while } \frac{\operatorname{ch}\theta_1}{\cos\theta_2}=\frac{OH^2+OS^2}{OH^2-OS^2},$$

from which, when the focal ellipse is drawn, the position of H and the tangents HP, HP′ can be drawn.

The angle AOQ is the amplitude function of a certain fraction $fK'$ of Jacobi's quarter period K′, with respect to the co-modulus $\kappa'$, the eccentricity of the focal ellipse; denoting AOQ by $\omega$, then, in Legendre's notation,

(13) $$F\omega=fK',$$

whence the fraction $f$ can be determined from his tables; so also the fraction $f'$ for AOQ′.

In connection with the dynamical interpretation there is an important point L in the tangent HP, such that, in Jacobi's notation for the Zeta-function,

(14) $$QL=OAZfK'$$
$$LV,\ LT,\ LP=OA\,(zs,\ zc,\ zd)fK'.$$

Expressed in Legendre's notation

$$ZfK'=E\omega-fE,$$

from which the position of L can be calculated by Legendre's Tables; and now a reduction of the elliptic integrals of the third kind in (7) will show that the apsidal angle

(15) $$\Psi=\frac{HL}{OA}K+\tfrac{1}{2}f\pi.$$

Integral (6) for the time $t$ gives

(16) $$mt=\int\frac{du}{\sqrt{2V}}=\frac{F\phi}{\sqrt{\tfrac{1}{2}(\operatorname{ch}\theta_1-\cos\theta_3)}}=\frac{OD}{OA}F\phi,$$

where

(17) $$\cos\theta=\cos\theta_3\cos^2\phi+\cos\theta_2\sin^2\phi,$$

a different use of $\phi$ to that employed in (8).

Thus if T is the time taken by the axis to swing between the extreme inclinations $\theta_3$ and $\theta_2$,

(18) $$mT=\frac{OD}{OA}K.$$

When H is at T, $N=n$, and the rosette curves described by Prof. Klein are obtained, in which the axis passes periodically through the highest vertical position, shown in Figs. 55, 56, 57. When H is at V, $N=n$ again, but now the axis describes an intermediate path, never becoming vertical. When H is at P, $N=-n$, and $\cos\theta_3=-1$; the axis now describes a new series of rosette curves, all passing through the lowest vertical position. These rosette curves are shown in one of Mr. T. I. Dewar's stereoscopic diagrams.

If we make $\kappa=1$, the focal ellipse becomes circular, and now $N=n=2\sqrt{AP}\cos\tfrac{1}{2}\theta_3$, and the axis reaches the highest vertical position asymptotically, the case represented in Fig. 58; and the hyperboloid shuts up into the axis, like a deformable napkin-ring.

Having settled upon a certain modulus $\kappa$, and a certain fraction $f$, which gives the tangent TPQ of the focal ellipse, we can examine the variety of cases which arise by taking different positions of H on this tangent.

In the spherical pendulum $N=0$, so that H must be placed on the pedal of the ellipse with respect to the centre O; and now

(19) $$\cos\theta_3=-\frac{OQ}{OH}=-\frac{\operatorname{dn}fK'}{\operatorname{dn}f'K'};$$

and similarly

$$\cos\theta_2=-\frac{\operatorname{cn}fK'}{\operatorname{cn}f'K'}, \quad \operatorname{ch}\theta_1=\frac{\operatorname{sn}fK'}{\operatorname{sn}f'K'}.$$

When H is on the tangent at B or B′, the curve described by points on the axis have cusps; when H lies between these points, the curves are looped, and the associated herpolhode has points of inflexion.

In steady precessional motion $\kappa=0$, and the focal ellipse coalesces with the line SS′; now $f=0$ and $K=\frac{1}{2}\pi$, so that the apsidal angle

(20) $$\Psi=\frac{HS}{OS}\tfrac{1}{2}\pi.$$

If $\mu$ denotes the constant angular velocity of precession,

$$\mu T=\Psi,\quad mT=\frac{OD}{OS}\tfrac{1}{2}\pi,$$

so that

(21) $$\frac{\mu}{m}=\frac{HS}{OD}.$$

The steady motion relations

(22) $$P=N\mu-A\mu^2\cos\alpha,\quad n=A\mu\sin^2\alpha+N\cos\alpha,$$

when $\alpha$ denotes, instead of $\theta_3$, the constant inclination of the axis to the vertical, will be found, on eliminating $\mu$, to be equivalent to the geometrical relation

(23) $$OQ\,.\,OQ'=\tfrac{1}{4}OD^2\sin^2\alpha,$$

so that O lies on a certain hyperbola, $xy=\frac{1}{4}OD^2$, referred to HQ, HQ′ the asymptotes as axes; thus given N and $\alpha$, a geometrical construction will determine the solution of the problem.

Having selected OD arbitrarily, the hyperbola is drawn, and then having laid off HQ′ to scale, draw Q′O at right angles to the asymptote HQ′ to meet the hyperbola in O; the tangent to the hyperbola at O will meet the asymptotes in S and S′.

The second solution will depend on the second point O′ in which Q′O cuts the hyperbola. To realise the state of motion shown in Fig. 28, the point O on the hyperbola must be close to the asymptote.

It is very desirable that a penultimate case of this nature should be worked out completely. We have the requisite analysis for the calculation of the algebraical case when there are 22 cusps, but the work would require the arithmetical courage of a Dewar, now unfortunately no longer available.

Supposing that in consequence of the friction of the pivot the motion has steadied down to uniform precession, then a $\begin{pmatrix}\text{following}\\\text{heading}\end{pmatrix}$ tap on the spindle, to $\begin{pmatrix}\text{hurry}\\\text{delay}\end{pmatrix}$ the precession makes O move along OQ and produces a focal $\begin{pmatrix}\text{ellipse}\\\text{hyperbola}\end{pmatrix}$ and the axis $\begin{pmatrix}\text{rises}\\\text{falls}\end{pmatrix}$.

A tap in the vertical plane makes O start out normally to the plane, and the lines HQ, HQ′ are now generating lines of Darboux's hyperboloid, in an intermediate position.

Once the limits $\theta_2$ and $\theta_3$ are assigned, and the corresponding apsidal angle $\Psi$, a regular curve satisfying these conditions drawn empirically will give an idea of the complete curve described by the axis.

But if it is desired to plot a number of intermediate points from tabular matter of the elliptic functions, we are baffled by the mixture of the real and imaginary arguments of the theta-functions required in the calculation of $\psi$ and $\phi$, although $\theta$ is readily calculated by equation (17). A courageous attempt at this computation is made in IV. 8, by Herr Blumenthal, but the hidden rocks of error are numerous and plentiful enough to make this procedure dangerous. If the calculation of a number of guiding points between the extreme points of a branch of the spherical curve is required, we had better utilise Jacobi's theorem, that the curve described in a horizontal plane round the vertical OG by the extremity of the vector OH of resultant angular momentum is a Poinsot herpolhode; and having plotted this herpolhode, the vertical plane defined by $\psi$ may be drawn perpendicular to the tangent HK of the herpolhode, while a simple relation of the form

(24) $$\cos\theta+2\frac{OH^2}{OD^2}=\frac{k}{2AP}=\text{ch}\,\theta_1+\cos\theta_2+\cos\theta_3,$$

will give the corresponding value of $\theta$, and hence the spherical curve, or its projection, orthographic or stereographic, can be plotted to any desired accuracy.

This theorem of Jacobi is almost self-evident when interpreted by means of Darboux's representation of the motion by the deformable articulated hyperboloid.

In this method the rod OG is held in the vertical position, and the point H is guided round the herpolhode; and then OG, connected by the articulation, will imitate the movement of the axis of the top; for a quadric surface can be drawn through H coaxial with the articulated hyperboloid, and normal to HP at H, and the squares of the semi-axes of this quadric will be, by a well-known theorem of solid geometry

(25) $$HQ\,.\,HV,\quad HQ\,.\,HT,\quad HQ\,.\,HP,$$

with proper attention to sign; and these being fixed lengths, the quadric is a fixed quadric.

Its equation may be written

(26) $$Ax^2+By^2+Cz^2=D\delta^2,$$

with

(27) $$\delta=HQ;\quad \frac{D}{A}=\frac{HV}{HQ},\quad \frac{D}{B}=\frac{HT}{HQ},\quad \frac{D}{C}=\frac{HP}{HQ}(\pm),$$

the $\pm$ sign being taken according as Q and V, T, P are on the $\begin{pmatrix}\text{same}\\\text{opposite}\end{pmatrix}$ sides of H.

An accent will serve to distinguish the case where a fixed quadric rolls on the plane through H perpendicular to HP′; and now we see why the same polhode described by H with respect to the axis of the articulated hyperboloid has associated with it two distinct herpolhodes.

(*To be continued.*)

## LIFE-HISTORY OF THE PARASITES OF MALARIA.

THE parasites which cause malarial fevers in human beings belong to a very homogeneous group, other species of which are found in certain bats and birds. The life-history of the three species of this group which have been completely studied is as follows. The youngest parasites exist as amœbulæ or myxopods within the red blood corpuscles of the vertebrate host. Each amœbula possesses a nucleus and nucleolus; and its movements vary in extent and rapidity with the species, but, in the case of birds, never encroach upon the nucleus of the corpuscle. The amœbulæ increase in size; and, as they do so, tend to lose their movements and to accumulate in their ectoplasm certain black granules, the pigment or melanin, which are the product of assimilation of the hæmoglobin of the corpuscle. In from one to several days the parasites reach their highest development within the vertebrate host, and become either (*a*) sporocytes or (*b*) gametocytes.

The sporocytes, which are produced asexually, contain spores which vary in number according to the species. The spores do not possess any appreciable cell-wall. When they are mature the corpuscle which contains them bursts and allows them to fall into the serum. They then attach themselves to fresh blood corpuscles, and continue the propagation of the parasites indefinitely in the vertebrate host. The residuum of the sporocyte, consisting chiefly of the pigment, is taken up by the phagocytes of the host for eventual disposal in the host.

The gametocytes, while in the blood of the vertebrate host, are still contained in the shell of the corpuscle.

In some species their general form and appearance is very like that of the sporocytes before the spores are differentiated; in another, however, they possess a special crescentic form. They continue to circulate in the blood for some days, or even weeks (according to the species), without change; but when they are drawn into the alimentary canal of certain suctorial insects, they undergo further development. In a few minutes after finding themselves in their new position, they break from the enclosing corpuscle by a kind of expansion, swell up slightly, and then commence their sexual functions. The male gametocytes emit a variable number of microgametes, which escape into the serum of the ingested blood, leaving behind a residuum consisting chiefly of pigment—as in the case of the sporocytes. The individual microgametes are delicate but very active filaments, consisting chiefly of chromatin, and sometimes seen to have a slight swelling at one point of their length —in the middle, when free, according to my observations. After escape from the male gametocyte, the microgametes seek the female gametocytes, which consist each of a single motionless macrogamete. One microgamete now enters bodily into a macrogamete and fertilises it, producing a zygote.

The further history of the zygote has been traced, as regards three species of this group of parasites, in certain kinds of mosquitoes. After being fertilised, it acquires the power of escaping the phagocytes of the ingested blood which surround it, of working its way through the mass of blood, of passing through the thickness of the stomach (middle intestine) of the mosquito, and of affixing itself to the outer surface of the organ. Here the zygotes are first found as oval cells about 8-10 $\mu$ in diameter. They still contain the granules of pigment which the macrogametes possessed before fertilisation. Growing rapidly, they soon acquire a capsule, and begin to protrude into the body-cavity of the mosquito. From an early period the nucleus divides into a number of portions—zygotomeres—each containing a fragment of chromatin. As growth advances, the zygotomeres become spherical blastophores, bearing each a large number of delicate, filamentous zygotoblasts on their external surface—each zygotoblast being affixed to the surface of the blastophore by one extremity. As maturity is approached the zygote, though still attached to the outer wall of the insect's stomach, protrudes freely into the body-cavity; its pigment tends to disappear; and lastly, the blastophores disappear, leaving the capsule packed with thousands of zygotoblasts. Maturity is reached in from one to three weeks, according to the external temperature, when the zygote reaches a size of 60 $\mu$ or more. The capsule then ruptures, pouring the zygotoblasts into the insect's blood.

The zygotoblasts are now seen to be delicate flagellulæ or mastigopods, about 12-16 $\mu$ in length, with the chromatin and one or two unstained areas in the middle, and two opposite tapering flagella. I have not, however, observed any notable movement in them, probably on account of the necessary dissecting medium. After being discharged into the insect's blood, these bodies are carried away by the current into all parts of the tissues, and finally effect an entry into the large grape-like cells of the salivary gland—especially the cells of the short middle lobe—where they accumulate in very large numbers. From the cells of this gland they pass into the duct which runs to the extremity of the middle stylet, the lingula, and thence escape during haustellation into the blood of a new vertebrate host. Here, it must be supposed, the flagellulæ attack the corpuscles and become the intra-corpuscular amœbulæ with which we started.

Four points require notice. (1) There are reasons for supposing that the gametocytes are or may be produced by the conjugation of two or more amœbulæ in one corpuscle. (2) The gametocytes of several species show, after escape from the corpuscle, one or more minute spherical bodies attached to their margin; which I assume to represent polar bodies. (3) The young zygote of at least one species (of crows) possesses, shortly after fertilisation, somewhat active powers of locomotion. (4) The mature zygotes of at least two species often contain large, brown, thick-shelled, cylindrical bodies, the nature of which has not yet been elucidated, and which may be parasitic fungi of the mosquito.

A brief history of how these facts came to be ascertained may be of interest. Laveran discovered the human parasites in 1880; and Danilewsky those of birds, some years later. Golgi established the law of endogenous reproduction by means of spores in 1885; and noted the differences in the various human species. Later, several Italian writers observed the distinction between the sporocytes and the gametocytes, but failed to understand the nature and object of these latter forms. The escape of the microgametes can be witnessed *in vitro;* and a dispute now arose as to the meaning of these bodies. Antolisei, Grassi, Bignami, Labbé and others held that they are products of death and degeneration *in vitro.* On the other hand, Laveran, Danilewsky and Mannaberg supposed them to represent the highest development of the organisms, while the last writer thought that they were meant for an exogenous saprophytic existence—without, however, suggesting the mode of their escape. In 1894 Manson concluded that the gametocytes are intended to continue the species outside the vertebrate host; and that they escape into the stomach of a suctorial insect, and then give rise to flagellulæ—as he considered the microgametes to be—which in turn develop in the tissues of the insect. He founded these views chiefly on the fact that the microgametes escape from the gametocyte only after abstraction of the blood from the vertebrate host. Laveran had already surmised that the mosquito is the alternative host of the human parasites; and Manson now claimed the mosquito as the suctorial insect referred to.

Early in 1895 I attacked the subject experimentally in India, on the lines laid down by Manson. Owing to the difficulty of the investigation and to the use of wrong species of mosquitoes, I failed for more than two years in reaching positive results. In August 1897, however, on employing two species of Anopheles fed on patients containing the crescentic gametocytes, I found the zygotes in various stages of growth attached to the wall of the insect's stomach. My work was now interrupted; but next year I succeeded in following out the life-history of the zygotes of one of the parasites of birds in their development in *Culex pipiens.* The zygotoblasts were found in the salivary glands of the mosquitoes; and lastly, in July 1898, I succeeded in infecting a large number of healthy birds by the bites of infected insects.

Meanwhile (1898) MacCallum had discovered the true nature of the microgametes by actually witnessing the sexual act *in vitro,* while Metchnikoff, and Simond had found microgamates also in *Coccidium oviforme* and *C. salimandrae;* so that the exact relationship between the gametocytes in the blood of the vertebrate (intermediary) hosts and the zygotes found by me in the mosquitoes (definitive hosts) became quite evident.

My results were published by Manson in August 1898, and were confirmed by Daniels, of the Malaria Commission of the Royal Society, in December. It was now easy to extend my observations to other species of the group, a work, however, which I was unable to undertake. In November and December 1898, Grassi, Bignami and Bastianelli cultivated two of the human parasites in a third species of Anopheles, *A. claviger,* Fabr., and succeeded in infecting several healthy persons. Shortly

afterwards Koch confirmed the principal observations which had been made.

If we can exterminate the malaria-bearing species of mosquito in a locality, we may expect to prevent the propagation of the parasites there; I trust, therefore, that these investigations will not remain without practical results.

It may be useful to add a note regarding the somewhat confused matter of the classification and nomenclature of the various species. I divide those of men and birds into two genera, named as follows:—

Family: HÆMAMŒBIDÆ, Wasielewski.

Genus I. *Haemamoeba*, Grassi and Feletti. *The mature gametocytes are similar in form to the mature sporocytes before the spores have been differentiated.*

Species 1: *Haemamoeba Danilewskii*, Grassi and Feletti. Syn.: *Laverania Danilewskii*, Grassi and Feletti, in part; *Halteridium Danilewskii*, Labbé; &c. Several varieties—possibly distinct species. Parasite of pigeons, jays, crows, &c.

Species 2: *Haemamoeba relicta*, Grassi and Feletti. Syn.: *Haemamoeba relicta* + *H. subpraecox* + *H. subimmaculata*, Grassi and Feletti; *Proteosoma Grassii*, Labbé; &c. Parasite of sparrows, larks, &c.

Species 3: *Haemamoeba malariae*, Grassi and Feletti. Syn.: *Haemamoeba Laverani*, Labbé, in part. Parasite of quartan fever of man.

Species 4: *Haemamoeba vivax*, Grassi and Feletti. Syn.: *Haemamoeba Laverani*, Labbé, in part. Parasite of tertian fever of man.

Genus II: *Haemomenas*, gen. nov. Syn.: *Laverania*, in part + *Haemamoeba*, in part, Grassi and Feletti. *The gametocytes have a special crescentic form.*

Species: *Haemomenas praecox*, Grassi and Feletti. Syn.: *Haemamoeba praecox* + *H. immaculata* + *Laverania malariae*, Grassi and Feletti; *Haemamoeba Laverani*, Labbé, in part; &c. Several varieties—possibly distinct species. Parasite of the irregular, remittent, pernicious or æstivo-autumnal fever of man.

The two species lately discovered by Dionisi in bats appear to belong, one to one genus, and the other to the other genus. Two species described in frogs do not contain pigment, and require further study. Grassi and Feletti's arrangement is very confused, chiefly on account of their combining *H. Danilewskii* with the crescentic gametocytes of *H. praecox* in a separate genus, *Laverania*. Labbé admits only one human species, and yet erects two genera for the avian species. The double spore-clusters of *H. Danilewskii*, on which he lays much stress, are not always found, and are at the best due, I think, merely to the presence of the nucleus compressing so large a parasite. There is little to justify generic differences between the four species of *Haemamoeba*. On the other hand, the last species given above is sharply divided from the rest.

The zygotes of three species have been found to develop in mosquitoes as follows:—

*Haemamoeba relicta* in *Culex pipiens*.

*Haemamoeba vivax* in *Anopheles claviger*.

*Haemomenas praecox* in two undetermined species of Anopheles in India, and in *Anopheles claviger* in Italy.

The development is the same in all, but slight differences in details have been noticed between *H. vivax* and *H. falcipara* in the mosquito.

The terminology employed above has been adopted in consultation with Prof. Herdman, F.R.S. Some of it has already been used in this connection by Mesnil, and by Grassi and Dionisi. Nuttall has recently given a very full account of the subject in the *Centralblatt für Bakteriologie*.

RONALD ROSS.

## SCIENCE AND EDUCATION.

TWENTY years have passed since Huxley said, at the opening of Mason College, Birmingham: "How often have we not been told that the study of physical science is incompetent to confer culture; that it touches none of the higher problems of life; and what is worse, that the continual devotion to scientific studies tends to generate a narrow and bigoted belief in the applicability of scientific methods to the search after truth of all kinds? How frequently one has reason to observe that no reply to a troublesome argument tells so well as calling its author a 'mere scientific specialist.' And, I am afraid it is not permissible to speak of this form of opposition to scientific education in the past tense." . . .

The exact applicability of these words in this year of grace is as good an example of the slowness of progress as could be wished. It is still urged almost as persistently as ever, and with the weight of university authority, that the only avenue to culture is by way of classics and the humanities. Has nothing come of the example of men like Huxley, Darwin, and the host of other widely-read, and deeply-educated, students of nature who, having borne their testimony, have gone over to the great majority?

These thoughts follow naturally from recent events in connection with the discussions and suggestions anent the constitution of the proposed Board of Education. The retirement of Sir John Donnelly from the secretaryship of the Science and Art Department led to the appointment of Sir George Kekewich to the vacant position, and for the future he will rule educational affairs both at South Kensington and Whitehall. In addition, two principal assistant secretaries were appointed, one for each of the departments referred to. These arrangements have disturbed the minds of the champions of that ill-defined section of educational work known as secondary education. After due representations Sir John Gorst stated, in the House of Commons, in reply to a question of Prof. Jebb, that a third official will be later appointed as assistant secretary for secondary education. This decision resulted in a correspondence which has brought to mind Huxley's addresses on education.

When a distinguished scholar and, on most subjects, broad-minded thinker, as Sir William Anson is, expresses himself in words like the following, which are taken from a letter in the *Times* of July 27, some sort of protest seems absolutely necessary.

"The attitude of those who are interested in secondary education, properly so-called, as distinct from elementary education on the one hand and instruction in science and art or technical education on the other."

"Scientific teaching alone will not produce the educated man, and the scientific expert may not be the best judge of the value of literary and historical studies, or of the respective parts which science and the humanities should play, even in an education which is mainly scientific."

"It is very important if the educational forces are to be brought into line, if the youth of the country are not merely to acquire some useful knowledge, but to become educated men—that where secondary education is given at all it should be given well, and that wherever it is given some one should watch over its interests and see that in the competition of humane and technical studies a due proportion is observed."

A number of unjustifiable conclusions may be derived from this letter; and it is therefore worth while to deal with a few of the points in it.

In the first place, it is tacitly assumed that some kind of secondary education exists in which instruction neither in science nor in art is given. The synonymous use of technical education and instruction in science and art must be passed over, though it provides a suggestive

index to the views of persons who are ever ready to pass judgment upon the educating capabilities of science and art. A course of instruction which ignores science and gives the cold shoulder to art is in one sense "secondary," but in no respect can it be called education. "Secondary education, properly so called," cannot exist distinct from "instruction in science and art." In fact, it is a little difficult to imagine what meaning Sir William Anson is intending to express. It would seem that he wishes to draw a distinction between the education offered in institutions of the grammar school type and those in which the curricula are at present directly governed by the Department of Science and Art. But it is a noteworthy circumstance that quite a number of old grammar schools provide, side by side with their classical work, classes in science which are actually subsidised by the much maligned department at South Kensington. And what is even more strange, judged from the point of view of Sir William Anson's letter, quite a number of these old grammar schools are also what is technically called "organised schools of science," which being interpreted, means that their time tables are modelled upon the regulations laid down in the Science and Art Directory, since they must be approved by the Inspector of the Department.

But the inference of the second quotation is of a more perverted type. "Scientific teaching alone will not produce the educated man," &c. Here again, something different from what is actually said is meant. Of course, Sir William Anson would agree that no teaching which is not scientific will do much towards educating anybody. As he himself said in a debate in the House of Commons on June 26, teachers should be taught how to teach, that is, should have "scientific" teaching explained to them. What is doubtless meant in the *Times* letter is, that instruction in natural science alone will not produce the educated man.

With this statement every man of science will agree; but neither will instruction in any single branch of human knowledge by itself educate. It would be just about as wise to attempt to educate a boy without introducing him to the beauties of our own incomparable national literature or that of some other great country, as it would to attempt to make him a cultured man and at the same time keep him ignorant of his place in the scheme of the universe and of the grandeur and beauty of the laws which govern things material. Culture is not the narrow business which the products of an exclusively classical training would have the world believe. Those authorities who claim for themselves alone the positions of priests in the temple of culture, are anachronisms—they should have lived in the Middle Ages. No education is worthy of the name which fails to endow its possessor with a sufficient breadth of view to give him a charitable demeanour towards every department of mental activity, and most of all to that wonderful accumulation of scientific knowledge to which we owe all that is best in life at the end of the nineteenth century. The man of science is as devout an admirer of literature, whether classical or modern, as any man. He is as ready with a profound admiration for the unique creations of the highest art, whether pictorial, musical, dramatic or what not, as any man. But he does claim that his goddess, science, is as worthy of attention as any other, and he has a right to expect that the reverence which he willingly extends to other deities shall similarly be shown by those who approach his particular shrine.

"The scientific expert may not be the best judge of the value of literary and historical studies or of the respective parts which science and the humanities should play, even in an education which is mainly scientific." So writes Sir William Anson. Possibly not, is the natural answer. But it is just as true that the classical (or historical) expert may not be the best judge of the value of scientific and artistic studies, or of the respective parts which the humanities and science should play, even in an education which is mainly classical. This is only a verbose way of saying that no individual can know everything. There is just as good reason, to say nothing stronger, for giving the control of the classical part of secondary education into the hands of a widely cultured and eminent man of science as there is for making a similarly great classical authority responsible for the government of the teaching of science or art. We surmise that no good will come of special pleading of this specious kind.

With the third quotation from Sir William Anson's letter given above there can be no disagreement if it is rightly understood. No man of science would imagine the youth of the country to be educated who had merely acquired some useful knowledge. We all want our secondary education to be given well. But let us look facts in the face. It is possible to spend twenty years in studying classics and to remain uneducated. We may become familiar with the histories of all the nations of the earth and be as far from culture as when we started the study. The secrets of nature may all have been laid bare before our understanding eyes, and yet we may still dwell with the Philistines. Let it be thoroughly understood that education and culture are greater than history, greater than classics, greater than science, but include them all, each in its proper place, and these narrow-minded bickerings as to the place of this or that subject of study will become things unknown.

One more reference to Huxley will define the scope of education from the point of view of a representative man of science. Speaking in 1868 to the working men of South London, Huxley defined the well-educated man: "That man, I think, has had a liberal education who has been so trained in youth that his body is the ready servant of his will, and does with ease and pleasure all the work that, as a mechanism, it is capable of; whose intellect is a clear, cold, logic engine, with all its parts of equal strength, and in smooth working order; ready, like a steam engine, to be turned to any kind of work, and spin the gossamers as well as forge the anchors of the mind; whose mind is stored with a knowledge of the great and fundamental truths of Nature and of the laws of her operations; one who, no stunted ascetic, is full of life and fire, but whose passions are trained to come to heel by a vigorous will, the servant of a tender conscience; who has learned to love all beauty, whether of Nature or of art, to hate all vileness, and to respect others as himself."

## *THE UNIVERSITY OF LONDON.*

THE supplementary vote of 65,000*l.* required in connection with the housing of the University of London in the Imperial Institute building at South Kensington was agreed to by the House of Commons on Monday.

A portion of the western end of the building is to be assigned to the Institute free of rent, and the eastern and central portion of the building will form the new home of the London University. The space which will be given to the University in the building will be far greater than was now enjoyed by that body. In consideration for the transfer of the lease to the Office of Works, the Government will provide funds sufficient to pay off the existing mortgage of 40,000*l.* and discharge the floating debt of 15,000*l.* In addition to the cost of structural alterations, estimated at 7000*l.*, the vote included 3000*l.* for the maintenance and repair of the buildings and for the purchase of the necessary furniture.

The Treasury Minute, dated July 13, containing particulars of the transfer, is reprinted below:—

The First Lord and the Chancellor of the Exchequer recall the attention of the Board to the question of the future housing of the University of London in the present Imperial Institute buildings, and they refer to the Board's Minute of February 16 last.

In pursuance of that Minute, conferences have been held between representatives of the University, of the Institute and of Her Majesty's Government, which have resulted in definite arrangements, subject only to adjustment on points of detail. The report of the Government representatives is now before the Board together with correspondence and memoranda connected with the subject.

Before proceeding to state the conclusions as affecting the University, the First Lord and Chancellor of the Exchequer desire to refer in general terms to the arrangements which have been made by Her Majesty's Government with the governing body of the Institute respecting the whole group of buildings now in their possession.

They are as follows :—

(1) The lease under which the buildings are held from the Commissioners for the Exhibition of 1851 will be transferred to the Commissioners of Works as representing the Crown, and the latter Commission will thereupon become responsible for maintenance, rates, custody and protection of the buildings. The Commissioners for the Exhibition of 1851 have assented to this arrangement.

(2) An agreed portion of the buildings will be assigned for the use of the Institute, free of rent, but with the responsibility for internal maintenance and repairs of that portion.

(3) The cost of removing the Institute from the portions of the buildings which they will surrender, including the necessary structural alterations, will be paid by Government.

(4) In consideration of the transfer of the lease, Government will provide funds sufficient to pay off the existing mortgage of 40,000*l.* on the building, and also to discharge a floating debt of the Institute, not to exceed in all 15,000*l.*

These arrangements will enable Her Majesty's Government to offer to the London University accommodation in the building which may roughly be described as follows :—

The eastern and central portions of the main block, including the principal entrance, vestibule and staircase, and the Great Hall; subject to occasional use by the Institute of certain portions of the central block when not required by the University, under regulations approved by the Chancellor of the University, and subject also to certain reservations in favour of the Government of India.

Also a portion of the upper floor of the inner block of building running east and west; and the temporary structure now standing in the South-Eastern Court.

This offer, which provides much more space than the present building in Burlington Gardens, has been accepted by the Senate of the University.

The principal structural alterations and adaptations required are—

(*a*) For the University—the provision of suitable lavatories and refreshment accommodation for candidates, and, if desired, the construction of a separate staircase giving access for candidates to examination rooms on the upper floors :

(*b*) For the Institute—the construction of a new entrance at the western end of the main block, the provision of new library and dining accommodation for Fellows, and the redecoration of rooms to which some of the services (Colonial and Indian) now provided in the eastern portion of the building will be transferred.

The University will occupy its new quarters under conditions substantially the same as those under which it now occupies the building in Burlington Gardens.

As regards accommodation for the practical examinations of the University in physics and chemistry, it has been agreed that this shall be provided in the new buildings about to be erected for the Royal College of Science, subject to arrangement between the two bodies as to dates of user. The Science and Art Department will take charge of, and keep in order, the instruments and appliances for the examinations.

The formal transfer of the lease will be carried into effect by the Solicitor to this Board; and the First Commissioner of Works should report at once as to the cost of the necessary works, as to arrangements for custody of the building, and as to the terms upon which the Institute should become tenants of the part of the building to be assigned to them.

The formal concurrence of the University and of the Institute, subject to settlement of details, has been obtained.

My Lords concur. They take note of the statements of the First Lord and Chancellor of the Exchequer, and desire that the necessary steps may be taken for carrying them into effect.

## *NOTES.*

THE seventy-first meeting of German Naturalists and Physicians will be held at Munich on September 17–23. According to the final programme of arrangements, the two general meetings will be held in the Königliche Hoftheater. At the opening meeting, on Monday, September 18, the following lectures will be delivered :—Dr. Nansen, on his journey towards the North Pole, and its results; Prof. v. Bergmann, Berlin, on the use of radiography to surgery; and Prof. Förster, Berlin, on the progress of astronomical thought during the past hundred years. At the second general meeting, on Friday, September 22, Prof. Birch-Hirschfeld, Leipzig, will lecture on science in relation to medicine; Prof. Boltzmann, Vienna, on the development of the methods of theoretical physics in modern times; and Prof. Klemperer, Berlin, on Liebig and medicine. There will be thirty-seven sections for scientific papers, seventeen being devoted to purely scientific subjects, and twenty to medicine. In a general meeting of the scientific sections Prof. Chun, Leipzig, will give an account of the results of the German Deep Sea expedition. A report will be presented by Prof. Bauschinger (Berlin), Prof. Mehmke (Stuttgart), and Prof. Schülke (Osterode) on the question of the decimal division of time and angle—a subject which will also be dealt with in a congress to be held in connection with the Paris Exposition next year. In a general meeting of the medical sections, Prof. Marchand (Marburg) and Prof. Rabl (Prague) will report upon the relation of pathological anatomy and general pathology to embryology, with special reference to the cell theory.

HITHERTO the overhead system of conveying electrical energy for driving tramcars has been the one most commonly adopted. The London County Council has, however, just decided to test underground systems of electric traction upon one of their lines. The recommendation of the Highways Committee, adopted on Tuesday, is as follows :—"That the estimate submitted by the Finance Committee for 10,000*l.* be approved; and that the Council do authorise the expenditure by the Highways Committee of that sum for the preparation of plans, specifications, and estimates, and other preliminary expenses, in connection with the reconstruction, for the experimental use of underground systems of electrical traction, of that part of the London County Council tramways between Westminster Bridge and Tooting; and that the committee be authorised to make all necessary arrangements for the purpose above referred to."

THE Duke of Bedford has been elected by the Council President of the Zoological Society of London, to fill the vacancy caused by the death of the late Sir William Flower.

UPON the recommendation of the Governor-General of India in Council, Her Majesty's Government has conferred upon Surgeon-General Sir J. Fayrer, Bart., K.C.S.I., Indian Medical Service, as a reward for distinguished and meritorious service, a good service pension of 100*l.* per annum.

THE Welby Prize of 50*l.*, offered for an essay on "The causes of the present obscurity and confusion in psychological and philosophical terminology, and the directions in which we may hope for efficient practical remedy," has been gained by Dr. Ferdinand Tönnies, whose essay, translated by Mrs. B. Bosanquet, appears in the current number of *Mind*.

PROF. GUIDO CORA, of Rome, has been elected (by Royal decree) a member of the Upper Council of the Geodetical Works of Italy (Consiglio Superiore dei Lavori Geodetici dello Stato).

THE expedition from the Liverpool School of Tropical Diseases, to which reference has already been made (p. 278), left the Mersey on Saturday in the steamer *Fantee*. Freetown will be the centre of experiments, with special regard to Major Ross's theory as to malaria being propagated by mosquitoes.

THE medical authorities of the Owens College and of the Royal Infirmary, Manchester, have been asked by the Chamber of Commerce to consider the advisability of forming a Manchester committee to co-operate with the Liverpool committee in the establishment and support of the Liverpool School for the study of tropical diseases.

THE annual congress of the British Medical Association was opened at Portsmouth on Tuesday. The president, Dr. Ward Cousins, delivered an address in which he sketched the progress made during the present century in medicine and surgery, with particular reference to recent discoveries in pathology and biology.

THE detailed programme of arrangements for the reunion of the Institution of Electrical Engineers in Switzerland, to be held in Switzerland from September 1 to September 9, has now been issued. The Council have decided that, with the exception of candidates for election, only members (of all classes in the Institution), and ladies and children accompanying them, can be authorised to take part. A number of visits to works and manufactories, and excursions to places of interest, have been arranged, and the programme provides opportunity for members f the Institution to spend a pleasant week in Switzerland.

THE sixth International Agricultural Congress will be held from July 1-8, 1900, in connection with the Paris Universal Exhibition of next year. The work of the congress will be divided into seven sections, as follows: (1) rural economy (agricultural credit, agricultural associations, land surveying, agrarian questions); (2) agricultural education (experimental stations, field experiments, &c.); (3) agricultural science (application of science to agriculture, agricultural improvements); (4) live stock; (5) practical agriculture (industrial crops and agricultural industries); (6) special crops of the South (silk production, early fruits and vegetables, perfume plants and colonial productions); (7) injurious insects and parasites (international measures for the protection of useful animals). Copies of the detailed programme may be obtained on application to the English representative of the International Agricultural Commission, Sir Ernest Clarke, at 13 Hanover Square, London, W.

THE Baly Gold Medal of the Royal College of Physicians of London, instituted in 1866 by Dr. F. D. Dyster, of Tenby, "in memoriam Gulielmi Baly, M.D.," which is awarded every alternate year on the recommendation of the president and council to the person who shall be deemed to have most distinguished himself in the science of physiology, especially during the two years immediately preceding the award, has been awarded to Dr. C. S. Sherrington, F.R.S., Professor of Physiology in University College, Liverpool.—The report of the Laboratories Committee of the College states that, since March 10 last, 1100 doses of antitoxin, each containing 2000 units, and 4425 doses, each containing 4000 units, for the treatment of diphtheria in the hospitals of the Metropolitan Asylums Board have been supplied and all the demands fully met. During this period 19,900,000 units have been supplied. During the same period five doses of 4000 units each have been supplied to the medical officers of health according to instructions received from the Metropolitan Asylums Board. Under the grant from the Goldsmiths' Company 459 doses of antitoxin containing 1,134,000 units have been supplied to the general an children's hospitals in or near London.—Dr. Arthur Foxwell, of Birmingham, will deliver the Bradshaw Lecture of the College on November 2. Dr. P. Horton Smith has been appointed Goulstonian Lecturer, and Dr. W. B. Cheadle Lumleian Lecturer for 1900, and Prof. W. D. Halliburton the Croonian Lecturer for 1901.

THE death is announced of Prof. Balbiani, professor of comparative embryology in the Collège de France.

THE expedition organised by the Peary Club, of New York, for the relief of Lieut. Peary in the Arctic regions started a few days ago. Prof. William Libbey, of Princeton University, is chief of the expedition, and with him are Prof. W. F. McClure, Dr. Arnold E. Ortman, Mr. Charles F. Silvester, and two representatives of the United States Coast Survey. The first object of the expedition is to take provisions and other supplies to Lieut. Peary. After the stores have been unloaded from the *Diana*, the return trip will be converted into a tour for scientific explorations. Chiefly deep sea investigations will be carried on, and specially prepared dredging apparatus have been provided for this purpose. It is expected that the party will return about October 1.

THE Bill having for its object the sanitary regulation of oyster beds has been withdrawn. When the order for the Committee stage of the Bill came before the House of Lords on Monday, Lord Harris said he had to move that the order be discharged. The intention of the Local Government Board in introducing the Bill was to protect as far as possible the public health from attack from diseased oysters; and the Board therefore selected as the local authorities by which the Bill was to be put into operation the councils of counties and boroughs which were concerned with the sanitary matters of their districts. But the Select Committee to whom the Bill was referred after the second reading decided that this was a matter which concerned more the health of the oyster than the health of the human being; and on a division they substituted the Local District Fisheries Committee, which looked after the well-being of fish for the councils of counties which were concerned with the public health as the authority in the Bill. But the Board of Trade, to whom the Bill was referred, decided that the change rendered the Bill impracticable; and in the circumstances the President of the Local Government Board does not intend to proceed further with the measure. The Bill was therefore withdrawn.

AT the meeting of the Institution of Mechanical Engineers held at Plymouth last week, a paper of much historic interest was read by Sir Frederick Bramwell, the subject being the South Devon atmospheric railway, preceded by remarks upon the transmission of energy by a partially rarefied atmosphere. Leaving out of consideration Savery's and such like machines for the raising of water by means of a partial vacuum produced by the condensation of steam, the first suggestion for transmitting energy by the rarefaction of air appears to have been made by Denis Papin in 1695. The matter lay in abeyance for more than a century, and then Mr. G. Medhurst proposed the propulsion of trains within a tube by means of air pressure. In 1824 John Vallance took out his patent, so very well known to all who have interested themselves in this subject of transmission of energy by the pressure of the atmosphere. Excep that Vallance proposed to move his train by the rarefaction of the air, his scheme was a mere repetition of that of Medhurst already mentioned. But the man who really developed this

mode of transmission of energy was John Hague. In addition to using a partial exhaust system to work cranes and tilt hammers, Hague applied this mode of transmitting energy to driving the machinery of powder mills, so as to remove the danger of steam-engine fire to any distance needed for safety. He also applied it to work the individual cutting-out presses and coining presses of a mint which he constructed for Rio Janeiro.

VALLANCE'S (Medhurst's) system of atmospheric railway was put to work in 1861, in the case of the "Pneumatic Postal Despatch," which was, in that year, laid down experimentally in Battersea Fields. In 1863 a line on this system was laid and got to work from Euston to the Holborn Post Office, a distance of about one and half miles, with the intention of going forward another mile to the General Post Office. In this case the ◠-shaped tube was as much as 4 feet high by 5 feet wide. The trains were "blown" and "sucked" backwards and forwards. A vacuous, or a pressure, condition of a few inches of water was found sufficient for the propulsion. In 1844, Mr. Brunel recommended the atmospheric system for the South Devon Railway, and by 1846 it was actually laid down nearly the whole way from Exeter to Newton. Four atmospheric trains ran on the line each way daily in 1847. In the life of Brunel, it is stated that 865 horse-power were required to do the work that he had a right to expect would have been done by 300 horse-power. By August 1848 the valve had begun to fail throughout its length. The cost had been 1160*l*. per mile, and in August 1848, just four years after Brunel had advised the trial of the atmospheric system, he reported that he did not recommend its extension, and, in fact, suggested it only as an assistant on inclines. The directors then suspended operations, and, afterwards, locomotives were used throughout.

SEVERAL popular articles on scientific subjects appear in the current number of the *Century Magazine*. Of particular interest are two articles on tornadoes, one by Mr. John R. Musick giving a description of a tornado witnessed by him at Kirksville, Missouri, in April of this year, and another by Prof. Cleveland Abbe on tornadoes in general. Mr. Musick's testimony as to the effects of the tornado is most astonishing. He says that when the storm struck the city, "doors, shutters, roofs, and even whole houses were sent soaring and whirling to a height of three or four hundred feet. I saw the wheel of a wagon or carriage and the bodies of two persons flying up into the storm-cloud. One house was lifted upwards to a height of over one hundred feet, when it seemed to explode into a thousand fragments, which went soaring, whirling and mingling with the other débris." Perhaps the most remarkable experiences were those of three persons who were caught up in the storm, and after being carried nearly a quarter of a mile, were let down so gently that none was killed. Several horses and many other animals were taken up by the storm and carried to considerable distances. One horse was carried two miles by the storm and alighted uninjured. An orchard south of the city had the trees torn up by the roots, carried four or five hundred yards, and piled into some vacant fields. An idea as to the fury of the wind may be formed by the size of the trees uprooted. Some of these were from twelve to eighteen inches in diameter, with roots ten feet in length The earth from which they had been jerked is said to have looked as if it had been torn by dynamite explosions.

As to the origin of tornadoes, Prof. Cleveland Abbe remarks that the point about which there has, perhaps, been the most uncertainty relates to the rotatory motion of the wind at the centre of the path of destruction. From the information he has been able to gather it appears that generally a west or north-west wind is blowing over the country, with a front of many miles in length, which trends south-west and north-east. This cool north-west wind pushes aside a gentler southerly wind that had been prevailing over that same region during the previous twenty-four hours. In the long belt, or trough, where these two winds meet, the warmer southerly wind is suddenly elevated and cooled by expansion, as also by mixture with the under-current of cold north-west wind. A cloud is thus formed, or in fact rolls of clouds, along the whole front of the area of north-west wind. At certain favourable spots the cloud soon becomes so large as to form a special indraft upwards through its centre, and the ascending wind must necessarily acquire a spiral ascending movement. The direction of rotation in this spiral is almost invariably the same as that of the hurricanes of the Atlantic Ocean, or the general storms attending the areas of low pressure that move eastwards over the United States, namely counter-clockwise.

THE Report of the U.S. Weather Bureau for the year ending June 1898 shows that no time has been lost in developing the Meteorological Service of the West Indies; arrangements have been made for observations being cabled twice daily from several islands to Kingston (Jamaica) and the central office in Washington, and negotiations are being carried on with the French authorities for the co-operation of the observers in Martinique. The maintenance of observations at Havana during the period of hostilities with Spain is also very gratifying. The important work of producing a thoroughly satisfactory kite has seriously occupied the attention of the Weather Bureau; sixteen stations have now been completely equipped, and the observers have all received a course of instruction in Washington. The observations hitherto made in the exploration of the upper air by this means contain much information that is new and of practical importance, independently of their value in making weather forecasts. The Canadian Meteorological Service has established a continuous record of the oscillations of the waves of Lake Ontario, which seem to show a connection with atmospheric conditions. These oscilliations are of much interest from several points of view, and the subject is engaging the attention of the U.S. Weather Bureau.

THE second annual report of the Council of the Röntgen Society shows that steady progress is being made. The Society numbers 148 ordinary members and five honorary members. Fresh evidence is continually received of the value of Röntgen rays in surgery, and there is much useful work open to the Society in the way of stimulating improvements in apparatus and in methods of investigation. The Council announce that Mr. William Noble has consented to be nominated as president for the ensuing year. He was among the earliest workers with X-rays, and has done useful service in radiography and on the physical side of the subject which it is the Society's object to advance.

THE volume of *Sitzungsberichte* of the Royal Bohemian Academy for 1898 contains, amongst other communications, a number of mathematical papers. These include notes on theory of curves, by C. Küpper (Prag); on a property of factorials, and remarks on trigonometric series with positive coefficients, by M. Lerch (Freiburg); on the residues of functions defined by differential equations of higher order, and on a system of semi-curvilinear coordinates, by Michel Petrovitch (Belgrade); on the infinitesimal geometry of certain plane curves, by J. Sobotka (Vienna); a note on spherical harmonics, by Franz Rogel (Barmen); and on the principal propositions of stereographic projection regarded as corollaries of Quetelet and Dandelin's theorem, by Carl Pelz (Prague).

FROM Messrs. Williams and Norgate we have received a copy of the *Sitzungsberichte und Abhandlungen* of the "Isis" Society, of Dresden, for 1898. It contains a paper, by W. Hallwachs, on determinations of the refractive indices of solutions.

In it the author gives an account of his differential method with grazing incidence, for which a double-trough refractometer has been used. The process in question has been applied to solutions of brome-cadmium, sugar, di- and tri-chloracetic acid and their potassium salts; and the author investigates the relation between the refractive index and the degree of concentration with a view of determining whether this is influenced to any extent by dissociation. The experiments show that such an influence, if it exists, is too small to be measurable with exactitude. This result is at variance in the case of bromecadmium with those obtained by Le Blanc and Rohland, but the discrepancy is attributed to an error.

THE twenty-first of the series of electrical papers published by W. G. Hankel in the *Abhandlungen der k. Sächs. Gesellschaft der Wissenschaften* deals with the thermo-electric and piezoelectric properties of certain crystals, including, amongst others, the formates of barium, lead, strontium and calcium, nitrates of barium and lead and sulphate of potassium. It is illustrated by several diagrams showing the distribution of positive and negative electrification over the faces of the several crystals.

THE general results of the magnetic survey of Sicily and the adjoining islands, commenced in 1890 by Prof. Chistoni and Signor L. Palazzo, were recapitulated in a communication by the latter observer to the *Atti dei Lincei*, vi. (2) 11. In *Terrestrial Magnetism* for June 1899, Signor Palazzo now gives a magnetic chart of Sicily showing the course of the isogonal and isoclinal lines, and the isodynamical lines for the horizontal component. The remarkable deviations produced in these curves by volcanic areas are well shown. Signor Palazzo having been appointed as a delegate at the International Magnetic Conference held in connection with the Bristol meeting of the British Association last year, availed himself of the opportunity for instituting a comparison between the magnetic instruments of the Italian Central Meteorological Office and those of Parc Saint-Maur and Kew. The results of this comparison have been published in the *Atti dei Lincei*, viii. (1) 8 and 9, and the author considers that these comparisons fully establish the trustworthiness of the Italian instruments and methods.

FOLLOWING in the footsteps of Japan and France, which countries in 1894 despatched scientific experts to investigate the outbreak of plague in Hong Kong, Germany decided in the year 1897 to send out a commission to study the plague in India, and in February of that year Dr. Gaffky, Dr. Pfeiffer, Dr. Stricker, and Dr. Dieudonné arrived in Bombay. The results of their labours have just been published in a volume of the *Arbeiten aus dem Kaiserlichen Gesundheitsamt*, and covers no less than 356 large quarto pages, whilst copious illustrations, coloured and otherwise, beautifully executed, serve to elucidate the text. The literature of previous outbreaks of plague in India has been carefully summarised by the authors, and the history of the recent severe epidemic has been traced as accurately as possible. As was to be anticipated, a large portion of the report describes the numerous experimental investigations undertaken by the experts, and the results of these researches form a valuable addition to the already bulky records obtained during previous inquiries. Prominence is given to the encouraging results obtained by Haffkine's method of preventive inoculation, and in this connection mention must be made of an official report recently published in India of inoculations against plague made from May to September last year in Hubli. The actual number of inoculations carried out by Surgeon-Captain Leumann and his staff amounted to some 78,000 altogether, and in summarising the results of his extended experience, Captain Leumann remarks that "inoculation arranges itself by the protection it affords in the foremost rank of methods for dealing with this disease."

AN article on "The Ethics of Vivisection," which appears in the current number of the *Edinburgh Review*, ought to be reprinted and widely distributed as a plain and dignified statement of fact as to the purpose of physiological research and the actual conditions under which it is carried on. So many misleading leaflets and tracts have been published by opponents of experimental work in physiology that all persons desirous of arriving at the truth of the matter should give consideration to the side or the case presented in the article to which reference has been made. In the course of the article the pain deliberately inflicte upon animals for mercenary motives, for sport, for food, for ornament, and other purposes is mentioned, and the very apt remark is made that "the only form of vivisection to which he [an opponent of vivisection] objects is that which furnishes not luxury, amusement, or vanity, but knowledge." But this only meets objections with a *Tu quoque*, and a specific statement of what civilised man owes to experimental physiology is more convincing to the logical mind. Such a statement is given in the article.

REFERRING to the results of the application of the experimental method advocated by Bacon and Harvey, the writer in the *Edinburgh Review* points out that physiologists and biologists "have enriched practical surgery with antiseptic methods and with anæsthesia; with control over hæmorrhage while operating; with a rational and successful treatment of aneurism and of glaucoma; with the power in not a few cases of removing a tumour even from the brain itself. In medicine proper, all that is summed up in the phrase 'heart disease,' all knowledge of arterial tension and its influence on the whole organism, have all been evolved gradually from the basis of Harvey's discovery. All our knowledge of nervous disease is based upon vivisectional experiments, from Charles Bell to Hitzig and Ferrier. Almost all our knowledge of the digestive processes, of angina pectoris and of methods of relieving it, has been gained through experiment. Practical medicine has been enriched through experimental research with such drugs as digitalis, cocaine, croton-chloral, nitrite of amyl; with the method of auscultation; with a knowledge of the cause of tuberculosis, typhoid fever, cholera; with the life-history of parasites; with the cause of myxœdema and related conditions and how to relieve them, and with a life-saving remedy for diphtheria. . . . It is, in fact, no figure of speech, but the simplest of truths, to say that everything of solid value in medicine and surgery is based upon knowledge gained by the experimental method." With this quotation we leave the article, convinced that it will be of much assistance in the spread of truth and the advancement of science.

A SHORT article, illustrated by reproductions from photographs, on the Medanos, or moving sand-hills of the Peruvian desert, is contributed to *Pearson's Magazine* by Mr. George Griffith.

THE following official botanical publications have reached us from the United States:—Sugar as food, by Mary H. Abel (U.S. Department of Agriculture, *Farmers' Bulletin*, No. 93); Mushrooms, II., by Prof. G. F. Atkinson (Cornell Univ. Agricultural Experiment Station, *Bulletin* No. 108); Notes from the South Haven sub-station; Vegetable tests for 1898; Bush fruits for 1898; Combating disease-producing germs; Killing the tubercle bacillus in milk (Michigan State Agricultural College Experiment Station (*Bulletins* Nos. 169-173).

THE *Journal of Applied Microscopy* continues, in the numbers most recently received (May-July), its useful *résumé* of recent work on microscopical technique:—Methods of plant histology,

by Prof. C. J. Chamberlain; Current bacteriological literature, by Prof. H. H. Waite; Normal and pathological histology, by Dr. R. M. Pearce; Neurological literature, by Edith M. Brace. Among original communications in the same branch of science we may mention an improvement in the technique of making blood-serum culture media, by Ernest C. Levy; and preparing sections of cochlea for microscopical examination, by M. T. Cook and H. H. Zimmermann.

Two new volumes have been added to the series of brochures published by MM. Georges Carré and C. Naud under the general title of "Scientia." The volumes are: "Les actions moléculaires dans l'organisme," by Prof. H. Bordier, and "La coagulation du sang," by Prof. Maurice Arthus. Each book comprises about one hundred pages, and shows the present state of knowledge of the subject dealt with in it.

The seventh volume of the renowned "System of Medicine," edited by Prof. Clifford Allbutt, F.R.S., has been published by Messrs. Macmillan and Co., Ltd. The volume continues the treatment of the subject of diseases of the nervous system. In the eighth volume, which will conclude the work, this subject will be completed, and the full sections on mental diseases and diseases of the skin will be added. When the final volume has appeared, it will be reviewed with others not yet noticed in these columns.

The additions to the Zoological Society's Gardens during the past week include a Purple-faced Monkey (*Semnopithecus cephalopterus*, ♂) from Ceylon, presented by Mrs. Usborne; a Common Badger (*Meles taxus*, ♀), British, presented by Mrs. F. Travers; a Zebu (*Bos indicus*, ♂) from India, presented by Mr. Smith Rylands; two Common Squirrels (*Sciurus vulgaris*), European, presented by Miss E. B. Sparrow; a Martinique Gallinule (*Ionornis martinicus*), captured at sea, presented by Mr. H. A. Pare; a Raven (*Corvus corax*), European, presented Mr. P. Stuart; two Tengmalms Owls (*Nycla tengmalmi*) from Norway, presented by Mr. P. Musters; an Adorned Terrapin (*Chrysemys ornata*) from Central America, presented by Mrs. R. J. Aston; a Common Snake (*Tropidonotus natrix*) from Italy, presented by Mr. T. G. Gunn; a Common Badger (*Meles taxus*) from Siberia, a Common Hamster (*Cricetus frumentarius*, European, a Ring-necked Pheasant (*Phasianus torquatus*) from Mongolia, four Horsfield's Tortoises (*Testudo horsfieldi*) from Central Asia, two Blackish Sternotheres (*Sternothaerus nigricans*) from Madagascar, a Japanese Terrapin (*Clemmys japonica*) from Japan, six Land Lizards (*Lacerta agilis*) from Central Europe, six Crested Anolis (*Anolis cristatellus*) from the West Indies, two Long-snouted Snakes (*Dryophis mycterians*) from India, a Common Snake (*Tropidonotus natrix*), two Common Vipers (*Vipera berus*), British, a Glass Snake (*Ophiosaurus apus*) from Southern Europe, deposited; two Common Wolves (*Canis lupus*, ♂ ♀) from Siberia, two Yellow-tufted Honey-eaters (*Ptilotis auricomis*) from New South Wales, two Nonpareils (*Cyanospiza ciris*, ♂ ♀) from North America, purchased.

Mars during Opposition 1898–1899.—MM. Flammarion and Antoniadi contribute to *Astr. Nach.* (Bd. 150, No. 3581) the results of their observations of Mars during the last opposition of the planet. The work was done at the Observatory of Juvisy, with an objective by Mailhat of 0·26m. aperture and 3·81m. focal length. The magnifying powers employed were 145, 224, 308, 411, and 607, the best images being obtained with the power of 308. Tables are given showing the progressive diminution in the extent of the polar caps, and of the whitening of the land surface under varying degrees of obliquity of the sun's rays. Two plates accompany the paper, showing the whole of the details observed, and in the description of these several differences are noted in comparison with the data given by Lowell.

As indicating the probable transparency of the Martian atmosphere, mention is made of the visibility of the Mare Tyrrhenum as a black marking quite up to the edge of the disc. The number of canals seen at Juvisy has been thirty-six, the majority of which were large and diffuse. Those easiest seen were Boréosyrtes, Cerberus and Styx. Several observations of gemination were made, which it is thought will throw some light on the cause of the phenomenon.

Photography of Nebulæ and Star Clusters.—At the meeting of May 3 of the Astronomical Society of France, M. L. Rabourdin, in the course of a paper on the history of the subject, showed some remarkably fine photographs of nebulæ and star clusters, and he gives a description of them, and of how they were obtained, in the July number of the Society's *Bulletin* (*Bull. Soc. Ast. Fr.*, July, pp. 289–299). The instrument was the large reflector of the observatory at Meudon, which was kindly placed at M. Rabourdin's disposal by M. Janssen. It has an aperture of one metre and a focal length of three metres, and is thus admirably fitted for the photography of faint objects of extended area. In the same number (pp. 299–304), M. Janssen furnishes some remarks on the above paper, entering fully into the question of astronomical photography, in the course of which he suggests obtaining a photometric scale for the measurement of the brightness of nebulæ by putting standard stars slightly out of focus, thus obtaining small circular discs on the plate instead of points, and then measuring the opacity of these circles.

## EXPERIMENTAL INVESTIGATIONS ON TELEGONY.[1]

### I. *Introductory.*

The belief in telegony, or what used to be known as the "infection of the germ" or "throwing back" to a previous sire, has long prevailed. It may for all we know be as old as the belief in "mental impressions," which has had its adherents since at least the time of the patriarchs. During the eighteenth century the "infection" doctrine was frequently discussed by physiologists, and since Lord Morton, in 1820, addressed a letter to the Royal Society on the subject, believers in "infection" have been increasing all over the world, with the result that one seldom now hears of breeders or fanciers who are not influenced by the doctrine, while physicians and others interested in the problems of heredity either as a rule take telegony for granted or see nothing improbable in the "infection" hypothesis.

It must, however, be admitted that, notwithstanding the criticisms of Weismann and others, very different views are entertained by the believers in telegony, not only as to the cause, but as to the results, of "infection." By some telegony is confounded with simple reversion or atavism, while the better informed generally assume that "infection" invariably results in the subsequent offspring repeating more or less accurately the characters of the first or of a previous sire. In a breeders' journal of some standing there appeared recently under the heading "Colour of Animals" the following sentence:—"Greys show in breeding a great tenacity of assertion. as they are few in comparison to other colours in the Stud Book, but they reappear and no doubt go back to the Arab, and prove telegony to be a fact" (*Live Stock Journal*, May 12, 1899, p. 588). This shows simple reversion is sometimes mistaken for telegony. In support of the view that "infec-

[1] "Experimental Contributions to the Theory of Heredity. A. Telegony." By Prof. J. C. Ewart, F.R.S., University of Edinburgh. (A paper read before the Royal Society, June 1.)

tion" is commonly supposed to lead to "throwing back" to a previous sire many instances could be given, but the following from an article on telegony by De Varigny will suffice. De Varigny states that an ordinary cat which had kittens to a tailless Manx cat subsequently produced several tailless kittens to a normal cat of her own breed (*Journal des Débats*, September 9, 1897).

An extended series of experiments with various kinds of animals has led me to the conclusion that if there is such a thing as telegony it is more likely to result in the subsequent offspring "throwing back" to an ancestor of the "infected" dam than to a previous mate. This view of telegony (which has not been insisted on hitherto) will be made at once evident by an example. A sable collie crossed with a Dalmatian produced three pups which in their coloration are extremely like young foxhounds; instead of numerous small spots each has a few large blotches. According to the common view of telegony this collie, if infected, should next produce with a dog of her own breed one or more Dalmatian-like pups. If, however, the offspring of a collie and a Dalmatian are like foxhounds the subsequent offspring to a collie of the same colour and strain could hardly be expected to present Dalmatian characters, *i.e.* show numerous small spots. But if "infection" as a rule results in the subsequent offspring "throwing back" either to the ancestors of the sire or the dam, it will be extremely difficult, if not in many cases impossible, to distinguish telegony from simple reversion.[1]

But though "infection," if it does take place, is likely, as a rule, to lead the subsequent offspring to resemble the ancestors of the dam, it may in certain cases possibly lead to their "throwing back" to a previous sire. This result might follow if the previous sire happened to be highly prepotent. For example, Highland heifers often produce to a Galloway bull hornless black offspring indistinguishable from pure Galloways. If infected by the Galloway bull, these heifers might afterwards produce Galloway-like calves when mated with long-horned bright coloured bulls of their own breed.

It is now commonly believed that if there is such a thing as telegony it results from the unused germ cells of the first (or previous) sire infecting—blending with—the unripe germ cells in the ovaries of the dam. Were this possible, the subsequent progeny would in all probability in a mild way resemble the previous sire, but if this is impossible then infection—due perhaps to some obscure change in the constitution or reproductive system of the dam—is more likely to lead to more or less marked reversion to the ancestors of the dam. All my observations point to its being impossible in the Equidæ for the unused male germ cells of the first sire to infect the unripe ova. The spermatozoa lodged in the upper dilated part of the oviduct of the mare are dead, and in process of disintegrating, eight days after insemination; they probably lose their fertilising power in four or five days. There is no reason for supposing that in the Equidæ they survive longer in or around the ovary. Further, though at the time of fertilisation there may be several large Graafian follicles in each ovary containing maturing ova, all these follicles disappear long before the period of gestation is completed. The subsequent foals are developed from successive new crops of ova into the composition of which it is inconceivable any of the spermatozoa of the first sire could by any chance enter. A study of the ovaries hence tends to confirm the view that "infection" (if there is such a thing) is as likely to cause reversion to a former ancestor of the dam as a "throwing back" to a previous sire.

Having made these general observations, it will be well next to consider critically the case of "infection" communicated in the letter to the President of the Royal Society in 1820[2] by the Earl of Morton. Though many other instances of supposed "infection" have been recorded, Lord Morton's mare may be said to still hold the field—the theory of telegony still mainly rests on the assumption that this historic mare was "infected" by a quagga some years before she passed into the hands of Sir Gore Ouseley and produced three "colts" to a black Arabian horse. One might even go further and without much exaggeration assert that the telegony hypothesis at the present moment mainly rests on an allegation by Sir Gore Ouseley's stud groom.

It has been generally assumed that Lord Morton's mare (a nearly purely bred chestnut Arab) was "infected" for two reasons (1) because the subsequent offspring were of a yellowish-brown colour and more or less striped, and (2) because, according to Sir Gore Ouseley's stud groom, the mane of one of the striped foals had always been upright, while in another it arched to one side clear of the neck. The presence of stripes in the subsequent offspring has never been questioned, nor yet is there any doubt that when Lord Morton in 1820 inspected the "colts" the mane in the filly was upright as in the quagga, while that of the colt resembled the mane of Lord Morton's quagga hybrid. There is, however, an absence of trustworthy evidence that the filly's mane had *always* been upright as alleged to Lord Morton by Sir Gore Ouseley's stud groom.

Were the evidence in support of this allegation satisfactory, there would I think be no escape from the conclusion that Lord Morton's mare was "infected" by the quagga. Hitherto the presence of stripes on the "colts" has generally been looked upon as affording strong evidence of "infection." Believers in telegony admit that stripes are not uncommon in Norwegian and certain other breeds of horses, but, with Mr. Darwin, they have taken for granted that they never or very rarely occur in Arabs.

I find, however, that though in Arabia dun-coloured horses are disliked and never used for breeding, stripes even in the most renowned strains are not so uncommon as is generally supposed. I have now a purely bred Arab filly of about the same colour as Lord Morton's filly, but, unlike the filly we have heard so much of, both the fore and hind legs are marked with distinct dark bars, and there are faint indications of stripes across the withers and a distinct dorsal band. The history of this filly (bred by Mr. Wilfred Scawen Blunt at Crabbet Park, Sussex, and very kindly presented to me) is well known for many generations; none of her ancestors could possibly have been "infected" by a zebra. The dun colour and stripes are doubtless the result of simple spontaneous reversion, for, unlike Lord Morton's mare, there is no history of a cross in her pedigree. This filly proves that even in high-caste Arabs of the best desert blood a dun colour and stripes may unexpectedly appear.

As to the occurrence of stripes in other breeds I could give, were it necessary, many instances. A year ago I had in my possession a light bay (or yellow dun) pony, which showed nearly as many stripes on the trunk as the Gore-Ouseley filly, and in addition had several interrupted narrow stripes on the forehead.[1] Moreover, the stripes on the Gore-Ouseley "colts," while agreeing with stripes occasionally seen in horses, differ in their arrangement from the stripes in the quagga. The stripes themselves are evidence of reversion, but nothing more; and seeing that pure bred horses sometimes show quite as many stripes, we are not justified in assuming that but for the dam of the "colts" having been first mated with a quagga the stripes would not have appeared.

Hence unless it is proved that the mane in the filly and colt were naturally erect, or nearly erect, the case for the "infection" of Lord Morton's mare will be lost. It may be well to quote the passage from Lord Morton's letter referring to the mane. It is as follows:—"That of the filly is short, stiff, and upright, and Sir Gore Ouseley's stud groom alleged it never was otherwise. That of the colt is long, but so stiff as to arch upwards and to hang clear of the neck, in which circumstance it resembles that of the hybrid. This is the more remarkable as the manes of the Arabian breed hang lank and closer to the neck than that of most others" (*Phil. Trans.* 1821).

I am not prepared to accept the allegation as to the manes for the following reasons:—

(1) I have had twelve zebra hybrids under observation, and in each case the mane, though erect to start with, always after a time arched over to one or both sides. The stud groom's statement, it seems to me, proves too much. If in the quagga hybrid and in all my horse hybrids the mane, sooner or later, falls to one side it is a little remarkable that in the pure bred two-year-old filly it had been always upright.

I may here mention that the hair of the mane of zebra hybrids is shed annually; it is for this reason that the mane in hybrids is never long enough to hang close to the neck.

(2) The mane in the drawing of the filly by Agassé is no

[1] That reversion ever occurs has been questioned by Bateson ("Materials for the Study of Variation") and others, but I have already (NATURE, February 9, 1899) proved beyond doubt that reversion can be easily induced by intercrossing distinct types, and I have recently heard of several instances of spontaneous reversion—reversion not induced by intercrossing.

[2] *Phil. Trans.*, 1821.

[1] See Fig. 36, "The Penycuik Experiments," A. and C. Black, 1899.

represented as upright, but as lying to one side. If the mane had remained erect during the first two years, by virtue of shedding its hairs, it could not very well have lost this habit and fallen completely over to one side subsequently, say, during the fourth year. From the mane being erect in 1820, and hanging to one side in 1821 or 1822, when Agassé's drawing was made, the presumption is that the mane of the "colts" had been cut some time before they were examined by Lord Morton.

Two years ago I had a bay Arab with a mane which was to start with short, stiff and upright; some months later it arched freely to one side, as in my zebra hybrids, and later still it hung lank and close to the neck.

(3) There is always an intimate relation in the Equidæ between the mane and the tail; when the mane is short and erect the upper third or so of the tail is only covered with short hairs, which, like the hairs of the mane, are annually shed. Lord Morton noticed nothing peculiar about the tail of the "colts," and the tail of both the colt and filly in Agassé's drawings is the tail of a high-caste Arab. This seems to me to warrant the conclusion that the filly's mane had been hogged some time before Lord Morton's visit.

It thus appears that the evidence in support of the belief that Lord Morton's mare was "infected" by the quagga is at the best far from satisfactory. The same may be said of the evidence in support of all the other supposed cases of telegony in the Equidæ—of, amongst others, Lord Mostyn's mare, referred to by Darwin ("Animals and Plants," vol. i. p. 435, 1875); of the mule-like mare in the Paris Gardens, referred to by Tegetmeier and Sutherland ("Horses, Asses and Zebras," p. 81); and of the African ass (*Equus asinus*), still in the Zoological Gardens (London), which now and then has a reddish-coloured foal, like the cross-bred foal she produced in 1883 to an Asiatic ass (*E. hemionus*).

Although I am now satisfied that Lord Morton's case throws little light on the telegony hypothesis, like many others I had no very decided views on the subject some years ago, and hence when arranging in 1894 to make a collection of horse embryos, I decided to repeat, as far as circumstances permitted, what is commonly called Lord Morton's experiment. For this purpose I procured early in 1895 three zebras and a number of mares. Two of the zebras died during the winter of 1895, but the third—a handsome stallion of the Chapman variety (*E. burchelli* v. *chapmani*)—still survives and is now thoroughly acclimatised.

During 1895 I only succeeded in mating the zebra with one mare, and hence there was only one hybrid born in 1896. During the last two years, however, quite a number of hybrids have made their appearance, and the dams of several of the hybrids have subsequently produced pure-bred foals. The time has hence come when some of the results of the experiments may with propriety be communicated to the Royal Society.

"II. *Experiments with West Highland Ponies.*" *By Lord Arthur Cecil, Orchardmains, Kent, and J. C. Ewart.*

The first mare mated with the zebra was a black West Highland pony (Mulatto), set apart for the telegony experiments by Lord Arthur Cecil. The better bred West Highland ponies are supposed to have descended from "Armada" horses, and are hence perhaps related to Mexican and Argentine horses, so often dun-coloured and partially striped. Mulatto's hybrid (Romulus, born August 12, 1896) is, on the whole, more a zebra than a pony both mentally and physically. He is especially remarkable in being more profusely striped than his sire (the zebra Matopo) in having a heavy semi-erect mane, which is shed annually, and in having a mule-like tail from the upper third of which the longer hairs are periodically shed. The body colour of the hybrid varies from a dark orange colour to a mouse-dun; the stripes, of a reddish-brown colour, on the head are dark brown or nearly black on the trunk and limbs.

In the number and plan of the stripes, the hybrid agrees more closely with the Somali zebra than with any of the Burchell zebras. Over the brow, *e.g.* there are narrow rounded arches instead of somewhat broad pointed arches as in his sire, the neck and trunk have quite double the number of stripes found in the sire, while over the croup in the position of the "gridiron" of the mountain zebra there were at birth irregular rows of spots, which in course of time blended to form somewhat zig-zag, narrow, transverse bands. The ears are nearly as large as in the sire, while the eyelashes are longer and distinctly curved. In his movements the hybrid resembles his sire, and like his sire he is always on the alert, very active and suspicious of unfamiliar objects. Further, in his call he agrees far more with his sire than his dam. In being profusely striped, Romulus differs greatly from the quagga hybrid bred by Lord Morton, in which the stripes were fewer in number than in many dun-coloured horses.

Mulatto's second foal arrived in July 1897, the sire, Benazrek, being a high-caste grey Arab horse. Like Lord Morton's colts, Mulatto's foal by the Arab horse, in make, action and temperament, agreed with ordinary foals, but it differed from the majority of foals in presenting quite a number of *indistinct* stripes—subtle markings only visible in certain lights. These stripes differed but little from the body colour, which varied from dark bay to brown. Though few references have been made to the occurrence of stripes in foals, they are, we find, far from uncommon. As is well known, Mr. Darwin once bred a striped foal by putting a cross-bred bay mare to a thoroughbred horse. This foal was for a time marked nearly all over with obscure dark narrow stripes, plainest on the forehead, but also distinct over the croup ("Animals and Plants," vol. i. p. 60).

There is no figure of Mr. Darwin's striped foal, but from the description given there can be little doubt that the markings were more abundant than in Mulatto's second foal. In this foal (as in Mr. Darwin's) the stripes became more and more indistinct, and by November they had almost vanished. Unfortunately the foal died when about five months old, and hence it is impossible to say whether any of the stripes would have persisted. It will be evident that Mulatto's second foal helped but little to clear up the vexed "infection" problem. Mulatto missed having a foal in 1898, but she recently produced at Knole, Kent, her third foal. The sire (Loch Corrie) of this foal belongs to the Island of Rum section of the West Highland ponies, and closely resembles Mulatto. The third foal has about as many stripes as the second. As in the second, they are most distinct over the croup and hind-quarters; and as in the second, they differ both from the markings in the previous sire, the zebra, and from the markings on the hybrid Romulus.

This third foal, which was born on May 6, 1899, seemed, like the second, to lend some support to the "infection" hypothesis. Fortunately, since it made its appearance, two other West Highland mares have had foals to Loch Corrie. These foals put all doubt as to the nature and significance of the stripes on Mulatto's second and third foals at an end.

One of the dams is of a brown colour, the other is nearly black. Though neither the brown dam nor the black has ever seen a zebra, both foals are marked in very much the same way as Mulatto's, and some of the stripes in one of the new foals look more like persisting than the stripes on Mulatto's third foal. Hence, in order to account for the markings on Mulatto's foal to the grey Arab, and on her foal to the black West Highland pony, it is unnecessary to fall back on the "infection" hypothesis.

"III. *Experiments with Shetland, Iceland, Irish, Thoroughbred and other Ponies.*" *By J. C. Ewart.*

An effort was made to cross four Shetland ponies with the zebra stallion, but I only succeeded in obtaining one hybrid. The dam (Nora) of this hybrid closely resembles, except in size, the Island of Rum ponies—she is a small edition of Mulatto. Her first foal, by a black Shetland pony, was of a dun colour, and nearly as striped as Sir Gore Ouseley's filly; her second is the most zebra-like of all my hybrids; her third closely resembles her sire, a bay Welsh pony. For some time after birth there were faint indications of stripes over the hind-quarters of this foal, but now it is a year old there are no markings or any other suggestions of a zebra. It is not a little suggestive that the foal bred from this pony before she was mated with the zebra was distinctly striped, while the subsequent pure bred foal has no stripes.

Of five Iceland ponies put to the zebra only one produced a hybrid. This hybrid was faintly striped, and showed less of the zebra than any of the others. The dam, a prepotent yellow and white (skewbald) pony, had first of all a light bay foal to an Iceland pony. Her third foal, by a bay Shetland stallion, is a skewbald, and in the size and arrangement of the brown patches closely resembles the dam. There is no hint whatever that the Iceland pony has been "infected" by the zebra.

Several Irish mares were put to the zebra, and two of them (bays) have first produced hybrids and subsequently pure bred foals. A cream-coloured Irish-Canadian mare unfortunately died before her hybrid foal was born. One of the bay mares

had a bay hybrid richly striped; the other a hybrid with but indistinct stripes. The subsequent foals—one by a chestnut thoroughbred horse (Tupgill), the other by a hackney pony (Mars Royal)—are bays, not only devoid of stripes, but affording no indication whatever that their dams had been previously mated with a zebra.

Although I experimented with seven English thoroughbred mares and an Arab mare, I only succeeded with one—a small chestnut. This mare produced twin hybrids last summer; she has this summer a foal to a thoroughbred chestnut horse (Lockstitch). One of the twins died soon after birth, the other, richly but unobtrusively striped, in its colour and make strongly suggests his dam. The chestnut mare's new foal neither in make, colour nor action in any way resembles a young zebra nor a zebra hybrid. In 1897 a bay mare by a bay Arab horse (Hadeed) was for some months in foal to the zebra. Since she miscarried in 1896 she has had two foals to a thoroughbred horse (Lockstitch). Neither of these foals in any way suggests a zebra. In this case the unused germ cells of the zebra had presumably a better chance of reaching the ovum from which the first of the two pure-bred foals was developed than is usually the case.

Attempts were made to cross Welsh, Exmoor, New Forest, Norwegian and Highland ponies with the zebra without success, and though a cross-bred Clydesdale has twice had a hybrid, she has not yet produced a pure-bred foal. The experiments, as far as they have gone, afford no evidence in support of the telegony hypothesis.

## *INVESTIGATIONS ON MOSQUITOES AND MALARIA.*[1]

I HAVE the honour to report the results of my observations since my arrival here on December 21, 1898.

Major Ross, I.M.S., first demonstrated and explained to me his method of dissection of the mosquito and the structures normally met with. From prepared specimens he then showed me the bodies met with after feeding these mosquitoes on birds infected with the proteosoma and the change day by day which they showed, ending with a demonstration of the germinal threads in cysts in the stomach wall, as seen in the fluids of the body and in cells in the salivary gland.

On my arrival there were in the laboratory, in test-tubes, series of mosquitoes fed on birds infected with proteosoma on the night of November 30, December 10, December 12, December 15, and December 20.

Of each of these series Major Ross dissected specimens for me after killing the mosquitoes with chloroform, and again demonstrated in these the same bodies that he had already shown me in prepared specimens; pointing out and demonstrating as he went on that in the older mosquitoes it was possible on cutting the thorax to observe the nature of the contents both of the coccidia in the stomach and of those of the cells of the salivary glands.

The points showed to me I readily observed.

From series of mosquitoes before mentioned I day by day examined both those which died and others I killed, and was as readily able myself to repeat the observations and in the earlier series to trace the changes in the size and nature of contents of the coccidia.

I also examined a large number of mosquitoes caught about the laboratory, and others which had been raised from larvæ. In no case did I find either coccidia in the stomach wall, germinal threads in the body fluids, or in the cells in the salivary gland; nor did I find "black spores" in them.

Major Ross informed me that his published results were based on observations made in the hot season when the temperature was 80° F., or more; and that now I should find the changes considerably slower, as it was the cool season, but that the sequence of events was the same.

My observations on the mosquitoes fed on December 20 and December 15 showed that this was the case, and that the coccidia advanced more slowly than the published results indicated. He also informed me that mosquitoes fed less readily and more difficulty was met with in rearing them to a spore-bearing age.

[1] Dr. Daniels's Report to the Secretary of the Malaria Investigation Committee of the Royal Society, London, on the results of observations made by him in Calcutta in conjunction with Major Ross, I.M.S. Dated Calcutta, January 23.

These difficulties the use of the incubator was only partially successful in obviating.

On the evening of January 1, following exactly in Major Ross's lines, I commenced a repetition of his main experiment. Two mosquito nets, free from rents, were taken, and in them were released a large number of grey mosquitoes reared from larvæ.

In the one, four birds were placed; in three of them on December 31 I had found proteosoma in large numbers, and in the fourth a moderate number.

In the other net two birds, in whose blood no proteosoma had been found, were placed; these two died two and three weeks later, and no pigment was found in their organs, and repeated examinations of their blood had failed to show proteosoma.

On January 2 none of the mosquitoes had fed, and on January 3 only two in the first net and eight in the second. On January 4, a warm night with a minimum temperature of 59·2° F., sixty-three mosquitoes were found gorged with blood in the morning, and were caught in separate test-tubes plugged with wool and placed in the incubator. Eighteen in the other net, where the non-infected birds were placed, the control series, were similarly collected; these were caught in the same manner and treated in the same way.

On the following two evenings, with minimum temperatures of 60·7° and 63·2°, sixty-eight and forty-six mosquitoes were fed on the infected birds and were kept for the preparation of specimens. Twelve mosquitoes were fed on the non-infected birds, and were used as additional controls so as to bring the number of the control on Blue Jay with numerous Halteridia.

On the third day the sixty-three, with the exception of those killed for examination or dead, were released inside a clean net free from mosquitoes, and birds free from proteosoma were also placed in it.

In the morning all mosquitoes found inside were collected, and most of them had fed well; the minimum temperature was 63·2° F.

This is the method Ross employs to re-feed the mosquitoes. If infected birds are used, you get a younger generation of coccidia; so I used sterile birds. The method works fairly well in warm weather; but there is always some loss, as the full number are not collected again in the morning. As the process is repeated over and over again, this loss becomes serious, the more so the longer the period required for maturation. In a frequently repeated process of this kind there is always the possibility of an outside mosquito getting in.

The mosquitoes were not fed on the following night, as they were full of blood; but most of them voided it during the night, and many died next day.

The remainder were given the opportunity of re-feeding every night after this; but a spell of cold weather ensued with minimum temperatures of 44° F.–49° F.; only on one night did it exceed 50° F., and on these nights few fed well or at all, and there was a consequent continued heavy mortality, only one being alive on the tenth day, and that subsequently escaped in the night.

This method of feeding is very unsatisfactory in exceptional weather of this kind; the mosquitoes in the day are kept warm in the incubator, and rapidly digest their food, whilst at night the cold renders them torpid and they do not feed.

The control mosquitoes were treated in exactly the same manner and fed on birds free from proteosoma. The last died on the thirteenth day.

The results of the two series are as follows:—

> Sixty-three fed on proteosomal birds.
> Forty-nine examined, three reserved for sections, one too much decomposed for satisfactory examination.
> Ten not accounted for, lost in the nets.

Of the forty-nine examined, two were killed on the first day—that is, under twenty four hours, and possibly under twelve hours, after they had fed. No coccidia were found in these. Two more were examined the following morning, under thirty-six and possibly under twenty-four hours after they had fed; no coccidia were found in these.

In two examined about 4 p.m., the minute pigmented coccidia were found; that is, under forty-six and possibly not more than thirty-four hours after they had fed on the infected birds.

The remainder were examined on the following days, the largest numbers, eighteen, on the fourth day and twelve on the seventh day, as on these two days those numbers died.

In every mosquito examined, with one exception, the coccidia were found usually in numbers, but in one there was only one coccidia.

The exception occurred on the ninth day; as by then they had been re-fed several times, it may have been an outside one which had effected an entrance.

So that out of forty-five mosquitoes fed on the infected birds and examined more than thirty-four hours after, forty-four contained coccidia.

This I may say is a more successful result than in the other series I have seen.

The other two sets of mosquitoes were used by all of us for preparation of specimens, and no record was kept of the number of failures. From my own examination only about three-fourths of them developed coccidia.

The treatment was a little different, and half of them were not incubated for several days.

Of the controls fed on birds free from proteosoma, thirty-eight in number and treated in the same manner, twenty-nine were examined and nine are unaccounted for—"lost in the nets." None of the twenty-nine were examined on the first day, but one was in the afternoon of the second day. The largest number examined were on what would correspond to the fourth and seventh days, *i.e.* seven and five; but there were four each on the fifth and sixth days.

It will be observed that these control mosquitoes were not, as the other series, collected on one, but on three nights. A very slight difference in breeze and light seems to affect the number who bite; or any extra restlessness on the part of the birds would have the same result.

In none of these twenty-nine were coccidia found. Of the eighteen fed on the Blue Jay with Halteridia, twelve were examined from two to six days after feeding and none contained coccidia.

The forms found on the second day measured 6–7 $\mu$, some of them a little more. They were oval bodies containing scattered granules of black pigment, and had a sharp, clear outline.

I incised the stomach, and by repeated washing and compression with a cover-glass was able, not only to wash out the contents of the stomach, but even to express the loosely attached epithelium, so as to leave the stomach as a transparent clear bag. To this outer wall the majority of coccidia remained fixed, though in one of the mosquitoes I observed some to escape with the epithelium. At no subsequent date could I ever detach any by this process, though some coccidia would be ruptured.

The next morning the smallest measured 10 $\mu$; some were 12 $\mu$. On the sixth day they were met with up to 30 $\mu$; by this time the pigment had absolutely as well as relatively diminished.

In another three days some of them reached 60 $\mu$; and in the last of the series examined (tenth day) there were coccidia measuring 70 $\mu$.

The coccidia could now be seen to project from the outer wall of the stomach; very few contained pigment, and that in small amount.

Some of the coccidia were clear and others had a granular appearance, but in none were there either black spores or germinal threads to be seen.

For the further development the early deaths of the mosquitoes from the inclemency of the weather rendered this series useless.

One of those which were infected on the night of January 5, and another infected on January 7, did reach this stage; and in the last of those first fed on January 5, which died on January 22, ruptured cysts were found by me in the stomach wall, as well as numerous cysts containing mature germinal threads, and these threads were also found in the body fluids and in cells in the salivary glands.

My observations are, therefore, mainly based on those infected November 30 and subsequent dates before my arrival, and on some infected December 22. The one infected on January 5 died on January 19, and the coccidia in it had an appearance of striation.

On adding salt solution (gr. xv. to the ounce) and pressing on the cover-glass, a projecting coccidium was ruptured; and the contents poured into the fluid, leaving the cyst wall still attached to the stomach.

The contents were seen to consist of a mass of shrivelled threads. This appearance in the other series mentioned I have frequently seen.

These threads, Ross's germinal threads, are sickle-shaped bodies about 14·15 $\mu$ in length, they stain with logwood or methyl blue, but not strongly; on adding water or Farrant's solution they lose their shrivelled appearance and become more rounded. Nearer one end than the other is an unstained portion (? nucleus).

They show no signs of movement; but as they are invisible in water and only become visible when shrivelled by the salt or stained, it may be doubted if they have been seen alive.

If a mosquito has its thorax incised when rather older than this, similar threads are found in the fluid exuded if salt solution is added to it.

In such a case ruptured cysts are found in the stomach wall.

The position as regards the salivary gland involves a difficulty which is not met with in any other part of the examination.

The dissection of the stomach is easy; that of the salivary gland in its entirety is not, and for some reason appears to be more difficult in the old infected mosquitoes. Any rough manipulation results in the detachment of the cells, and little more than the duct is left. In most cases, however, one entire gland, or portions of both, can be exposed in fair condition even in old infected mosquitoes.

In every case where this was done and germinal threads were found in the body-fluids, the germinal threads were also found in some of the cells in the salivary gland, and no similar threads have I found in a large number of salivary glands examined by me in mosquitoes bred from larvæ, free about the laboratory, or in the earlier stages of coccidial infection.

The affected cells can be distinguished with a low power, as they have a granular appearance, whilst the unaffected cells are quite clear.

With a high power, if not very numerous, the isolated germinal threads can be clearly distinguished and recognised by their peculiar shape and shrivelled appearance (the examination must be made in salt solution). If numerous, the individual threads can be no more distinguished than in the coccidia, but, as in those, pressure on the cover-glass will rupture the cell, and the germinal threads are then poured out.

The threads do not fill the cell. There is a faintly granular crescentic portion on the side most remote from the duct, which in many cases at least is free. The part of the cell in which the threads lie must be nearly fluid, as it permits oscillations ot the threads to take place.

On these points I have satisfied myself by repeated examinations, though the appearances are by no means difficult to make out; and have gone at some length into the question, as so far we have found no satisfactory method of making permanent preparation. All the preservatives at our disposal wrinkle up the delicate cells, with the exception to some extent of weak formation solution; and I have no confidence in that as a means of making permanent specimens.

The whole gland is never involved. In one dissection made by Ross the cells in both middle lobes and in no other part of the gland contained the threads. In several cases where one gland has been exposed entire, the middle lobe alone has been involved; but in the majority all that can be stated with certainty is that the cells in one portion of the gland contain threads, and in other portions they do not.

The following specific observations made by myself on mosquitoes dissected by Major Ross, Dr. Rivenberg of the American Mission, who is working with Dr. Ross, and myself may be of interest.

(*a*) Coccidial cysts full of apparently mature germinal threads, no ruptured cysts, no germinal threads in the body fluids or salivary glands. Two observations.

(*b*) Cysts full of germinal threads, other ruptured empty cysts, germinal threads in body fluids, germinal threads in salivary glands. Over twenty observations.

(*c*) Empty cysts in stomach wall, germinal threads in body fluids of thorax. Germinal threads in salivary glands. No cysts still containing germinal threads. Two observations.

(*d*) Empty cysts only in stomach wall, no germinal threads in body cavity, no germinal threads in well-exposed salivary glands. One observation, the mosquito had been infected four weeks before death.

These observations fully confirm Ross's statements in every point. They indicate that the threads are formed in the coccidia, that they escape on the rupture of these into the body-cavity and

are again collected in the salivary glands. I should have liked to extend the series, but the continued cold weather renders it improbable that I shall be able to do so before I leave.

With your permission I should like to publish an abstract of this, confirming Ross's work; and to this Major Ross consents.

In case you should consider this advisable, I am, to avoid delay, forwarding an abstract to Dr. Manson, with a request to him to forward it to the *British Medical Journal*, if your consent is granted.

The infection of birds free from proteosoma by the bites of mosquitoes.

On December 20, the day before my arrival, twenty-two birds were examined and found free from proteosoma. On that night some of these were used for feeding the mosquitoes which had been infected on November 30 and on the 24th and subsequent days; the remainder of the birds were used for feeding the mosquitoes first infected on November 30 and December 10, 12 and 15. In other mosquitoes of this series germinal threads were found in the salivary glands; and the ones which fed, when examined later, gave the results indicated in paragraph 9.

On December 30 Dr. Rivenberg and myself examined these birds; three of them had proteosoma, two in large numbers.

On January 4 I examined them all except one, which died on January 2; in that the heart's blood contained no proteosoma, and the organs were free from pigment.

Five more of these had now proteosoma, all very numerous. On January 6 and 7 I again examined them; three more had proteosoma, all very numerous.

On January 9 no more cases had developed; but on January 18 one of them had numerous proteosoma, whilst many of the ones which had been infected had recovered, and the others now showed few proteosoma.

Thus twelve out of twenty-two birds became infected, or 54 per cent. This compares unfavourably with Ross's earlier results, as in his published series twenty-two out of twenty-eight were infected, or 79 per cent. But it is to be remembered that at the time he was working the germinal threads were found in a week; whilst in December the development was much slower, and now takes at least twice the time. It is much easier to keep the mosquitoes alive for one week than longer, while in the hot weather mosquitoes bite more readily.

These results are less unfavourable if compared with the normal proportion of birds infected with proteosoma at this season. Thus Ross out of 111 wild birds found proteosoma in 15, or 13·5 per cent.; whilst I find at this season only one with proteosoma out of 30, or 3·3 per cent.

It is possible that in the cold season the birds have a greater power of resistance; and this is rendered more probable by the short duration of the proteosomal attack in my infected birds. Of these twelve, five died within the first week. In three, in which also the proteosoma had been very numerous, none could be found ten days after the invasion; in one, in which they were never numerous, none could be found on the fifth day.

In the other three, very few are now found, though at first they were numerous.

The recovery of these birds and the death of the mosquitoes fed on them diminishes the chances of much future work on this line in the time remaining to me here.

Mention has been made of the differentiation of the contents of the coccidia previous to the formation of the germinal threads into clear and granular; the second of these can be traced day by day into those forming the germinal threads. This differentiation was clearly visible in my series. Instead of germinal threads in a minority of the coccidia, in most mosquitoes, when the germinal threads are mature, black tubular bodies are found in cysts with otherwise clear contents.

These were met with frequently in the series of mosquitoes infected in November and December. Most of these contained some coccidia with black spores; though in few all the cysts contained germinal threads. In some cysts these black spores are numerous and occupy the entire cyst; in other cysts there are only a few. In most cases germinal threads are not found in the same cyst; but there have been a few cysts in which it has been doubtful whether there are germinal threads also in the cyst, or whether there are overlying escaped threads from a neighbouring capsule.

These black spores are very resistent; I have seen some kept in water for months by Ross with no visible change, and they will withstand irrigation with liquor potassæ.

When the cysts are ruptured the spores are found all over the body, but not in cells; nor do they seen to accumulate in any one part of the body.

The most plausible view of the nature of these black spores seems to be that held by Major Ross, viz. that they are "resting spores," and that through them by another cyst the proteosoma can be propagated in conditions unfavourable for direct propagation by injection into a warm-blooded animal.

In that case three courses suggest themselves:

*a*. From them arise bodies capable of non-parasitic life and possibly of reproduction, but capable at certain stages of their existence of introduction into a warm-blooded host by inhalation through drinking water, or even by injection by a mosquito or other blood-sucker transferring them from the medium in which they live directly.

*b*. That they may be ingested by mosquito larvæ, and in them undergo such development as will result in the formation of germinal threads in the adult, which in turn might be injected into the bird.

*c*. That they may, when swallowed or inhaled by a warm-blooded host, so develop as to reach the circulation and pass into the sporulating phase.

Such experiments as have been made are inconclusive; and it is obvious that till the nature of these "black spores" is determined we cannot exclude, even for the proteosoma of sparrows, the possibility of some one of the many alternative possible channels of infection, some of which would only require the occasional intervention of an intermediate host.

Still less are we justified in concluding that malaria in man can only be acquired from the mosquito, or devoting our exclusive attention to that channel.

## UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Dr. E. H. Starling, F.R.S., has been elected to the Jodrell professorship of physiology in University College, London, in succession to Prof. E. A. Schäfer.

Dr. Sutherland, assistant professor of pathology, Glasgow, has been appointed professor of pathology in St. Andrews University, in succession to Prof. Muir, recently appointed to Glasgow.

For some time past the School Management Committee of the London School Board have been considering communications sent to them with reference to the metric system. It has now been resolved to send a memorandum to the Education Department containing proposals for amplifying the teaching of the system by a definite curriculum for each standard.

The Board of Education Bill was read a third time in the House of Commons on Tuesday. An animated discussion took place upon the various clauses of the Bill, and several amendments were proposed, but no changes of any importance were made. One of the amendments moved had for its object the omission of the words which empower the Board of Education to employ for the purpose of school inspection "other organisations" besides the Universities. These words were struck out in the House of Lords, and re-inserted in Grand Committee in the Commons. The proposal to again delete the "other organisations" was negatived.

At a meeting of the council of the City and Guilds of London Institute held on Monday it was resolved to confer the Fellowship of the Institute upon Mr. William J. Pope for the valuable and original chemical research work which he has done since he gained his diploma of associate of the institute in 1890; and upon Mr. Arthur E. Childs for the services he has rendered in developing several new branches of engineering industry since he gained his diploma in 1891. The Fellowship is conferred by the council upon those who, having obtained the associateship of the institute and spent at least five years in actual practice, produce evidence of having done some original and valuable research work, or of having otherwise contributed to the advancement of the industry in which they are engaged.

The Agricultural and Technical Education (Ireland) Bill was read a second time in the House of Lords on Monday. Lord Ashbourne, in moving the second reading of the Bill, said its object is to promote and foster agriculture and all the kindred interests, and also to promote technical education. The Bill in its mechanical part proposes the creation of a department com-

posed of the Chief Secretary, a vice-president, and officials, for whose appointment powers are given. To them will be transferred various powers now scattered over other boards. As to the financial resources to be placed at the disposal of the new department, it is calculated that the total income from all sources will amount to from 160,000*l.* to 170,000*l.* a year; and this money will be applied to aiding and encouraging agriculture and other industries and technical instruction. The board to be formed under the Bill will be aided and advised by three bodies to be called into existence—a council of agriculture, a board of technical instruction, and an agricultural board—which will have very wide and important duties to perform. Speaking broadly and generally, the income of the board is to be devoted as follows: 55,000*l.* to technical instruction; 10,000*l.* to the improvement and development of the sea fisheries; and the remainder to agriculture and rural industries.

## *SOCIETIES AND ACADEMIES.*

### PARIS.

**Academy of Sciences**, July 24.—M. van Tieghem in the chair.—Presence of iodine in notable proportions in all plants containing chlorophyll of the Algæ class, by M. Armand Gautier. As a result of numerous estimations of iodine in Algæ containing chlorophyll it was found that iodine is a constant element of the protoplasm of these plants, both in sea water and fresh water, the latter, however, containing much smaller quantities of iodine. Thus, where 100 grams of dried marine Algæ give 60 mgr. of iodine, the same weight of fresh water Algæ gave only 0·25 to 2·4 mgr.—On the theory of partial differential equations, by M. N. Saltykow. The author's previous work on this subject was restricted to equations resolved with respect to partial differentials. Since, however, the solutions of the equations may offer considerable difficulties from the point of view of practical applications, the theory of any equations whatever in involution is here given.—On indeterminate equations of the form $x^\lambda + y^\lambda = cz^\lambda$, by M. Edmond Maillet.—On a correspondence between two ruled spaces, by M. A. Demoulin.—On the magnetic field inside a hollow cylinder traversed by a current, by M. W. de Nickolaieve.—On the dielectric cohesion of rarefied gases, by M. E. Bouty. In a preceding note it has been shown that when a tube containing a rarefied gas is placed in an electrostatic field, there is a critical intensity of field, $f$, below which the gas acts as a perfect dielectric and above which the gas allows the passage of a discharge. In the present paper the relation between the critical intensity, $f$, and the pressure of the gas, $p$, is quantitatively examined, and the result expressed in the form

$$f = A\left(1 + Bp + \frac{C}{p}\right),$$

where A, B, C, are constants, B, and perhaps C, being independent of the nature of the gas, and A increasing with the molecular weight of the gas.—The instantaneous disappearance of the Kerr phenomenon, by MM. H. Abraham and J. Lemoine. By the use of a rotating mirror M. Blondlot has shown that the time that elapses between the suppression of the electric field and the disappearance of the Kerr effect is less than 1/40,000 of a second. In the present paper it is shown by a different method that the time cannot exceed 1/10,000 of this, namely 1/400,000,000th of a second.—On the isomeric states of chromic acetate, by M. A. Recoura. A detailed description of the normal acetate, possessing the properties of an ordinary metallic salt, and the violet acetate, in cold solutions of which alkalis give no precipitate.—Mixed copper-silver salts, by M. Paul Sabatier. The salts described are the basic nitrates, $3Cu(OH)_2.2AgNO_3$, and $2Cu(OH)_2.2AgNO_3$, two similar chlorates, the sulphate, $3Cu(OH)_2.Ag_2SO_4$, and the thiosulphate $2Cu(OH)_2.Ag_2S_2O_3$.—On the purification of iridium, by M. E. Leidié. The method suggested is based upon the conversion of the metal into chlorides, and subsequent use of sodium nitrite. The iron and lead are first precipitated as oxides, and gold as the metal, the solution then containing double nitrites of ruthenium, rhodium, and iridium, and sodium osmiate. The ruthenium and osmium are eliminated as volatile peroxides, and the rhodium and iridium converted into the double chlorides with sodium chloride, these being readily separable.—On a double nitrite of ruthenium and potassium, by M. L. Brizard. The new salt described has the composition $Ru_2H_2.(NO_2)_4.3KNO_2.4H_2O$. On the reducing properties of boron and aluminium, by MM. Duboin and Gauthier.—Oxidation of propylglycol by bromine water, by M. André Kling. By the reaction of bromine upon propyl-glycol,

$$CH_3.CH(OH).CH_2OH$$

in sunlight, an appreciable amount of acetol,

$$(CH_3.CO.CH_2.OH),$$

is produced.—On some opium alkaloids, by M. Émile Leroy.—Determinations of the heats of combustion, neutralisation, and solution of codeine, thebaine, papaverine, and narcotine.—On the elimination of nitrogen and phosphorus in infants nourished at the breast, by M. Œchsner de Coninck.—On dichlor-3.4-butanoic acid, by M. R. Lespieau. Of the two possible formulæ for this acid,

$$CH_2.Cl.CH(OH).CH_2.CN \text{ and } CH_2Cl.CH(CN).CH_2.OH$$

experimental evidence is given in favour of the former.—Action of bromine on isobutyl bromide in presence of anhydrous aluminium bromide and aluminium chloride, by M. A. Mouneyrat. Starting with the monobromobutane,

$$CH_3.CH(CH_3).CH_2Br,$$

by the action of bromine in presence of aluminium bromide, four substances are obtained, isobutylene bromide, a tribromoisobutane, boiling at 130° under 26 mm. pressure, tetrabromoisobutane, all in small quantities, and, as chief product, a tribromoisobutane boiling at 112°, probably $CH_3.CBr(CH_3).CHBr_2$.—On the composition of the albumen of the carob bean; production of galactose and mannose by hydrolysis, by MM. Ed. Bourquelot and H. Hérissey.—Experiments on the state refractory to the serum of the eel, by MM. L. Camus and E. Gley. The natural immunity of the hedgehog to the poisonous action of eel serum is now shown to be also possessed by other animals, such as the common frog, toad, chicken and pigeon. This immunity, which the authors have shown to be due to a specific resistance of the red blood corpuscles, is called by them cytologic immunity, to distinguish it from the humoral or acquired immunity resulting from the production of antitoxin in the immunised animal.—Experimental researches on an agglutinine produced by the albumen gland of *Helix pomatia*, by M. L. Camus.—Intra-uterine transmission of vaccinal immunity and the antivirulent power of the serum, by MM. Beclère, Chambon, Ménard, and Coulomb.—On the branchial respiration in Diplopods, by M. M. Causard.—On the breccias of the Briançonnais, by M. W. Kilian.—On a bathymeter founded upon the use of Crusher cylinders, by MM. Charbonnier and Galy-Aché.

## FLORAS FROM THE ROYAL GARDENS, KEW.

*Flora Capensis: being a Systematic Description of the Plants of the Cape Colony, Caffraria, and Port Natal (and Neighbouring Territories), by various Botanists.* Edited by W. T. Thiselton-Dyer, C.M.G., C.I.E., LL.D., F.R.S., &c., Director, Royal Gardens, Kew. Published under the authority of the Governments of the Cape of Good Hope and Natal. Vol. VI. Hæmodoraceæ to Liliaceæ. Vol. VII., Parts I. and II. Pontederiaceæ to Gramineæ. (London: Lovell Reeve and Co., 1896–97.)

*Flora of Tropical Africa.* Edited by W. T. Thiselton-Dyer, C.M.G., C.I.E., LL.D., F.R.S., &c., Director, Royal Gardens, Kew. Vol. VII. Hydrocharideæ to Liliaceæ. Published under the authority of the First Commissioner of Her Majesty's Works and Public Buildings. (London: Lovell Reeve and Co., Ltd., 1898.)

IT should not be necessary at this time of day to emphasise the fact of the imperial character of the Royal Gardens, Kew, still it would appear there are many inhabitants of Great Britain whose notion of the value of this establishment is limited by their desire for a local public park suited to the recreation of dwellers in and about London. Several incidents have of late shown this—witness the recent preposterous proposal brought forward in the House of Commons to throw the gardens open to cyclists! Suggestions of this kind are on the face of them, to those aware of the true character of the gardens, too absurd for discussion, yet there is an element of danger in this appeal to the selfish instincts of that large body of pleasure-seekers who are veritable Gallios in their contempt for science, especially when its just claims place an obstacle to the gratification of their pleasure whims. It is hardly conceivable that any First Commissioner of Works—and he is the Minister responsible for the gardens—would ever assent to such modification of the traditional character of the gardens as concession to the demand above referred to, which may be taken as symptomatic of a craze, would mean; yet in these days of political opportunism, and with a prospect of its even greater development, the preservation of the noble heritage the nation possesses in the Kew of the present becomes a question not altogether free from anxiety in the minds of those who know the services Kew renders and is capable of yet rendering to the Empire. Perhaps the surest way of avoiding disaster in the future is by making known far and wide what are its real functions and how they are discharged, for through the education of public opinion alone can an effective checkmate be given to any movement destined to sacrifice the scientific features of Kew at the altar of popular pleasure.

It is not the intention to discuss here the whole of the functions that belong to and are discharged by Kew—its value as an unrivalled microcosm of the vegetation of the world, its example as a school of horticultural practice, its position as a training ground for young gardeners, its use as an index of the products of the vegetable kingdom and as a nursery and centre of distribution of economic plants for the benefit of our Colonies—but to direct attention to the continued progress, indicated by the titles of the volumes cited above, of the large undertaking to which the energy and foresight of its first Director, Sir William Hooker, committed Kew—namely, the issue of a "Series of Floras" under the authority of the Home or Colonial Governments. Botanists are familiar with what has been already done by Kew towards the carrying out of this programme. The Australian Flora by Bentham and Von Mueller, that of Hong Kong by Bentham, of New Zealand by Dr. Hooker, of Mauritius and the Seychelles by Baker, of the West Indies by Griesbach, and the recently completed British Indian Flora by Sir Joseph Hooker are a tribute alike to the industry and talent of the botanists who have taken part in their production and to the importance of Kew in focussing botanical knowledge, as well as to the labours of our countrymen in the exploration of regions opened up to our occupation. The appearance of the volumes mentioned above has been particularly welcome, inasmuch as they denote a renewal of progress after a pause. The Flora Capensis was arrested after the publication of the third volume in 1865 by the death of Harvey, who, with Dr. Sonder, was its principal author; and of the Flora of Tropical Africa, the last of the three volumes brought out by Prof. Oliver appeared in 1877. The Director of Kew is to be congratulated upon having surmounted the hindrances which have contributed to the delay in continuing these Floras, and he will, it may be hoped, be encouraged to contend with and overcome all obstacles that may as it seems, threaten a steady advance to the conclusion of the works.

The volumes and parts before us are not in sequence with the volumes that have already appeared. As Sir William Thiselton-Dyer points out, once the plan of a work of the kind is settled it is immaterial what part first appears, and he has exercised a wise discretion in giving early attention to those groups of plants which are abundantly represented in our gardens, and which have consequently compelled special attention on the part of members of the Kew staff. The Monocotyledons have been therefore selected for first treatment in the resumed work upon the Floras, and we have the benefit of the ripe experience of Mr. Baker in the elucidation of the Liliaceæ, Irideæ, Amaryllideæ and allied orders, which are so popular in horticulture and form so large an element of the plant-life of South Africa, and to a less extent in the area embraced within the scope of the Tropical African Flora; Mr. Rolfe brings to the enumeration and description of the Tropical African Orchideæ a rare knowledge of the order; and Mr. N. E. Brown describes the Tropical African species of Disa as an expert. Tropical African Hydrocharideæ have fallen to the share of Mr. C. H. Wright, and the Cyperaceæ of South Africa find a sound critical exponent in Mr. C. B. Clarke; the account of the Gramineæ of the same area is in the able hands of Dr. Stapf, and should be completed in the next part of the Flora, for which we trust we shall not have long to wait.

 Q

In the continuations of these Floras we have the same standard of excellence to which preceding volumes have accustomed us, and which we therefore look for in publications coming from Kew. Their issue will be a boon not only to the professed botanical world, but also to all those who are interested in the many plants now known in, and still coming into cultivation from, Africa ; and they should give a great stimulus to the further investigation of the vegetation of Africa and to the introduction of interesting and beautiful plants to the horticulture of the world.

No one looking at these volumes can fail to notice that their production at Kew, where a collection of living plants in a garden is associated with one of dried specimens in a herbarium, gives additional value to them. The necessity of the latter as a guide to the accurate determination of the nomenclature in a scientific garden is apparent ; the service of the former as an adjunct to the herbarium by affording means for the study of the living plants in cases where the dried specimen can seldom be satisfactory is clearly brought out in the account of the groups of succulent monocotyledons treated of in these Floras. If all descriptive botanists were able, as is possible at Kew, to look at the dry bones of the plants with which they deal with some consideration of the form that clad them when alive, we should be spared much of that prolific synonymy which is the bane of the systematist. It is the possession of the finest collection of living plants along with a like one of dried specimens, through which it can contribute as in these Floras to the advance of our knowledge of the vegetation of the globe, that gives Kew an absolutely unique position as the leading botanical institution of the world, a position it has achieved in little over fifty years through the scientific ability and remarkable administrative capacity of its successive Directors, Sir William Hooker, Sir Joseph Hooker, and Sir William Thiselton-Dyer.

## *STATISTICAL METHODS APPLIED TO BIOLOGY.*

*Die Methode der Variationsstatistik.* Von Georg Duncker. Pp. 75, with 8 figures in text. (Leipzig : Wilhelm Engelmann.)

THIS pamphlet, a reprint from the *Archiv für Entwickelungsmechanik*, is an attempt to render the formulæ and results of the statistical method somewhat more accessible to German biologists than they are, for example, in Prof. Karl Pearson's original papers. In the first part a complete outline is given of the fitting of frequency curves, normal or skew, to observed statistics, and in the second part a similar outline of the theory of correlation. The whole of this extensive ground is covered, however, in some sixty octavo pages, necessitating a degree of compression too great for satisfactory results. Proofs are necessarily almost wholly omitted, several difficulties likely to occur to beginners are slurred over, and there is more than one absolute blunder.

If $y = \phi(x)$ be any frequency curve, the frequency of deviations lying between $x - \frac{1}{2}c$ and $x + \frac{1}{2}c$ is given by the integral of the frequency-function $\phi(x)$ between those limits. If, and only if, $c$ be very small, we may replace this integral by the product $y.c$ to a close degree of approximation. Hence, in any practical case of recording the distribution of frequency where we have to choose an arbitrary unit of grouping $c$, this should always be made as small as possible. If this be done, and if the number of observations be large, the observed frequency polygon closely approximates to a continuous curve, and the element of area round any ordinate differs very slightly from $y.c$. Moreover, the process of obtaining the moments of the observed frequency polygon by treating the observed frequencies as isolated loads, then differs very slightly in result from the process of continuous integration by which the moments of the theoretical curve were calculated. But if the element of grouping be not small, the element of area round $y$ may differ very sensibly from $y.c$, and the process of calculating moments by treating group frequencies as isolated loads is not even a rough approximation to continuous integration. Hence Prof. Pearson's original preference of the moments of the trapezia system (*Phil. Trans.* A, 1895, "On Skew Variation," &c.), and Mr. W. F. Sheppard's papers on moment calculation (*Proc. Lond. Math. Soc.*, vol. 29, and *Journal Roy. Statistical Soc.*, vol. 60, 1897). This difficulty, due to the grouping, is entirely passed over by Herr Duncker. A series of observations giving only five base elements $c$ is fitted without remark to a normal curve (Fig. 2). In every case the ordinates of the fitted curve are calculated only for the abscissæ of the observed ordinates, their tops are joined up, and the polygon so obtained called the "theoretical frequency polygon," as in Figs. 1, 2, 3—a procedure of somewhat dubious use in any case, and quite illegitimate where the elements are as large as in Fig. 2. If the author had not missed this fundamental point he would not, perhaps, have been so puzzled by Prof. Pearson's use of first one and then another method of calculating moments. It is a pity that all the arithmetical examples given of fitting frequency curves refer to cases of discontinuous variation, as these are naturally the material least suitable for representation by continuous curves.

There seems a corresponding lack of clearness in some fundamental points of the theory of correlation. The various formulæ for correlation coefficient, regressions, &c., are given, but the author nowhere clearly points out their meanings and limitations in cases of non-normal correlation. It is not noted that for complete independence the condition $r = o$ is, in general, necessary but *not sufficient*. The values of partial correlations are given, but it is not noted that only in normal correlation (so far as we know) is the partial correlation the same for every array. The correction given on p. 48 for reducing the product sum about an arbitrary pair of axes to the product sum about the mean is surely absolutely wrong ; the different sums given are all of different dimensions. If $S_0$ be the value of the sum for axes through the mean, $S_1$ its value for the arbitrary axes

$$S_0 = S_1 - N. \bar{x}\bar{y},$$

where N is the number of observations and $\bar{x}\bar{y}$ are the coordinates of the mean with reference to the arbitrary axes. Of course this expression, and method of getting $S_0$, is quite well known, not novel as Herr Duncker seems to think.

Again, complete correlation does not subsist only when "every single deviation of the one characteristic corresponds to a precisely equal deviation of the other" (p. 43), but whenever the deviations are in any constant proportion. This definition, moreover, ought only to be held to apply to the case where the means of arrays lie on straight lines.

We do not like the definition of correlation as a "Beziehung . . . welche bewirkt. . . ." This is not a statistical definition, and confusion arises if the word be used carelessly, sometimes in one sense and sometimes in another. The definition of the correlation coefficient on p. 54 is much better; but why does the author call it a "morphological definition"? It is purely statistical.

The statement that it is mainly correlation which maintains the type ("die Korrelation ist es hauptsächlich, welche den Typus einer Formengemeinschaft aufrecht erhält") is a very pretty error; possibly due to the fact that biologists use correlation in a more "intensive" sense than statisticians do. Statistical correlation has absolutely nothing whatever to do with the maintenance of type. The type is described by the coordinates of the mode. If $X_0$ be the modal size of any organ in a parent, $Y_0$ the modal size of the same organ in the offspring, the "type is maintained," or constant, whenever

$$X_0 = Y_0,$$

and this relation is quite independent of the correlation. The correlation between parent and offspring might be absolutely zero, *i.e.* every single parent's offspring might be a fair sample of the whole population, and yet the type might remain absolutely fixed; or, on the other hand, parent and offspring might be perfectly correlated, and yet the type change entirely. This is at least *formally* possible. Thus, in the extreme case of alternating generations A B A B . . ., there might in the statistician's sense be perfect correlation—perfect inheritance—between A and B, although A and B differ absolutely.

Of course in a work of the present kind, written chiefly for drawing attention to the work of others, one does not look for much that is original. There is a curious approximate relation given by the author between geometric mean, arithmetic mean, and standard deviation (p. 38), a relation discovered empirically and given without proof. If

$G$ = geometric mean,
$M$ = arithmetic mean,
$\sigma$ = standard deviation,

then *approximately* in many cases

$$\sigma^2 = M^2 - G^2.$$

The relation depends solely on all deviations being small compared with the mean, and admits of a simple algebraical proof.

Amongst small points we have marked, we would like the term "individual" variation suppressed, as it is frequently misleading, and surely not equivalent to "spontaneous"; the word "variant" seems to us unnecessary and misleading in the case of continuous variation where arbitrary groupings are used; the distinction between "Rasse" and "Formeneinheit" (p. 17) (". . . erstere nothwendig in mehreren Merkmalen, letztere in einem einzigen differiren") is surely inadequate; a preliminary calculation of the mean before calculating the moments of a frequency distribution (p. 18) is quite unnecessary, as the mean is given by the first moment; and the author is unfortunately in error in ascribing to the present writer (p. 52) the extension of the formulæ of correlation to several variables.

We regret that this notice has had to be for the most part fault-finding, as the author has undertaken a useful and somewhat thankless task, and we believe that, notwithstanding our criticisms, the pamphlet will be useful in extending a knowledge of the statistical method in Germany. There is a bibliography of 111 items at the end of the pamphlet, a feature which will render it useful to English readers as well as German. We are, of course, in sympathy with the author's aim, and hope he may have the opportunity of revising some of the points we have noted in a second issue. G. U. Y.

## TEXT-BOOKS OF PHYSICS.

*Physics, Experimental and Theoretical.* By R. H. Jude and H. Gossin. Pp. xiii + 926. (London: Chapman and Hall, Ltd., 1899.)

THE increasing study of science in schools has been the cause of a considerable crop of text-books of elementary physics, but there is still the want of a more advanced book on the subject. This want Mr. R. H. Jude has endeavoured to supply, and as far as can be judged by a glance through his book, supplemented by a more careful examination of a few chapters, he has succeeded in giving us what promises to be a very useful work both to teachers and students. Experience only can show whether he has hit on the right standard of difficulty, and whether the learner will find the explanations sufficiently clear and complete; but there seems no reason to doubt it, considering that the work is an English adaptation of a book by Prof. Gossin, which is apparently much used in France.

Originally intended to be a translation, the volume before us contains many new articles and chapters, and the translated portions have been amplified. The first volume treats of mechanics, heat and sound. The following remarks are not intended to be special criticisms of this particular book, but rather are suggested by it and put down as matters for consideration, being of general interest to teachers of science.

It seems a little doubtful to me how far a book which contains a somewhat advanced treatment of experimental physics should enter into questions of elementary mechanics. It is impossible to believe that a student who can follow the method of treatment given in the chapters on heat in this volume should not be familiar with the parallelogram of forces, and the construction of the common pump. Some portions of dynamics, such as moments of inertia, must, of course, be included, and it may be argued that it is better to present a complete than a partial statement of mechanical principles. This is true, and of course a good deal might be said about the parallelogram of forces and velocity that is worth reading at any stage in a student's career, but what strikes me in this volume is that the standard of treatment does not quite correspond,

and that a book which enters into questions of entropy and thermodynamic relations might pass a little more rapidly over baby mechanics. This remark applies specially to the illustrations, some of which are of the most elementary character and even childish.

This brings me to the second point I wish to submit to the consideration of authors. A number of illustrations in modern books seem to me to be put in for the sake of interrupting the text by a picture rather than for the sake of explanation. There is, for instance, the usual illustration which pretends to illustrate the fact that all bodies fall in vacuo with the same velocity. A long glass tube with a tap at the lower end, two hands holding it, and about a third of the way downward a small black dot and another dot a little bigger about a millimetre higher up. I suppose that the dots represent bodies, and that their closeness is intended to show their falling together. Unfortunately, in the present instance the stopcock at the bottom is open according to English ideas (though closed if they mean to be French taps), so that the intelligent student unacquainted with the habits of the French plumber would carry away the idea that bodies fall together in air at atmospheric pressure. But without laying stress on this, I should like to know the opinion of my colleagues, whether they seriously believe that students are assisted by illustrations of this nature. Some psychological freak may account for its being so; but it seems odd to me, and is worth investigating. I have marked several other instances of illustrations which seem to me to be of the same type. On the other hand, the diagrams illustrating graphic methods in thermodynamics are clear and well chosen.

Finally, I am not quite sure I like the introduction of exercises and examples. Examinations, no doubt, are a necessity, and I have no objection to books written specially to push boys through them, but the present book is too good to serve in this manner, and one does not quite like being constantly reminded of the fact that ninety-nine per cent. of students only study physics because they are obliged to do so, and I have never yet seen a student, or seen any one to my knowledge who knows a student, who will work through an example without the stimulus of examinations upon him. I should prefer to see the examples collected in a special appendix at the end. Two small points I may draw attention to, as the author may wish to correct them in another edition. Speaking of solar heat, Lord Kelvin's theory of falling meteorites is mentioned, but nothing is said about the now generally accepted theory of Helmholtz that the sun's contraction by his own gravitation is sufficient to account for the keeping up of his temperature.

Speaking of the fact that the surface of liquid at rest is a horizontal plane, the author considers it in § 127 to be a sufficient proof that the image of a plumb line is observed to be a prolongation of the line itself, for it is said that "an object and its image are symmetrical only when the reflecting surface is plain." Will not a spherical surface do equally well, if the plumb line passes through the centre of the sphere? If I add that in the figure on p. 108 the meniscus of a mercury column is wrongly drawn, inasmuch as its curvature diminishes as it approaches the glass sides, I have exhausted all the blemishes which the critical mind can discover. But I started to praise rather than to criticise, and must conclude with the hope that the volumes on light and electricity will soon be ready for publication.

ARTHUR SCHUSTER.

## OUR BOOK SHELF.

*The Tides Simply Explained: with Practical Hints to Mariners.* By the Rev. J. H. S. Moxly, B.A., T.C.D., Chaplain to the Forces; Chaplain to Chelsea Hospital. Pp. viii + 151. (London: Rivingtons, 1899.)

THIS is a paradoxical work which may do harm owing to the standing of its author. He openly avows himself at war with the scientific world:—

"What is this strange hallucination that has taken possession of the minds of great mathematicians? I have quoted several truly absurd statements and arguments of our teachers in my first chapter. I wished to show my readers, by many infallible proofs, that the idols of authority, to which we have been bowing down, are not the correct thinkers we have supposed them to be" (p. 58).

He could not be much more severe if scientific men were a general-staff. His method of "infallible proof" of the fallibility of these idols is simple; he quotes a sentence or a paragraph, and then says:

"This is, of course, sheer nonsense! It is too absurd a statement to deserve any answer" (p. 8).

Having disposed of existing theories by this drastic process, he proceeds to give his own theory of the tides:

"The moon and earth are being drawn together by the attraction of gravity, yet they do not come together. There must therefore be a force equivalent to the force of attraction, but acting in an exactly opposite direction, which keeps the earth and moon asunder. It does not matter what we call it! 'Centrifugal force' will do for a name for it, if you like. The point for us is that the force does exist—must exist, and that it is exactly equal to the attractive force, but opposite in direction. *Well, then, if the attractive force raises a tide under the moon, the force opposite the attractive force will produce a similar effect on the opposite side of the world*" (p. 52).

The sentence in italics (which are mine) is one of the neatest things in paradox I have come across. It is scarcely surprising that the man who could invent it should be able to deduce from this amazing premiss the correct expressions for the tide-generating force at any point on the earth's surface. But then he throws this advantage to the winds, by despising the horizontal component as insignificant, and electing to work with the vertical component only, because it suggests to him an attractive but hopelessly false analogy. We are to imagine a gigantic power taking the world in its grasp, as a schoolboy would squeeze a ball between his finger and thumb. The horizontal component of tide-generating force is compared to a butterfly harnessed to Nelson's Column; but, to suit his own ideas as regards vertical force, Mr. Moxly makes the butterfly a schoolboy and Nelson's Column an india-rubber ball.

After stating this general theory, Mr. Moxly examines some cases of what have been unfortunately called "abnormal" tides, and triumphantly gives explanations of them; partly wrong, and partly such as any one could deduce from a general knowledge of the locality; and, as this is done with some skill, it is to be feared the book may mislead some of the "mariners" to whom it is addressed. It is to be hoped that before trusting Mr. Moxly they will wait until he has produced detailed and successful tide-tables for any given port deduced fairly from his own theories.

H. H. T.

*Defective Eyesight.* By Dr. D. B. St. John Roosa. Pp. ix + 186. (New York: The Macmillan Co. London: Macmillan and Co., Ltd., 1899.)

Dr. Roosa's book is pleasantly written and easy to follow, but it is not very clear what particular place in ophthalmic literature the book is intended to occupy. From the superficial manner in which each subject is treated it would appear to be intended for the instruction of the junior student.

But a student's manual on the refraction of the eye in which no mention is made of retinoscopy, and the ophthalmoscope is only casually referred to as being unnecessary in most refraction cases, is certainly somewhat incomplete.

Most people will agree with Dr. Roosa in condemning the permanent wearing of prisms in the treatment of heterophoria. But the statement that want of balance of the external ocular muscles never causes asthenopic symptoms, is contrary to the experience of the majority of ophthalmologists.

We thoroughly endorse the author's views as to the practical value of the ophthalmometer, though he overstates the case when he says that, to a competent observer, no mistake is possible in the estimation of astigmatism with this instrument. Those who have used both ophthalmometric and other methods with the same patient, in any considerable number of cases, will agree with Adolphe Javal, jun., that corneal astigmatism often differs from the total astigmatism by 0·5 to 0·75 dioptre.

*The Lancashire Sea Fisheries.* By Charles L. Jackson, M.I.C.E., &c. Pp. viii + 85. (Manchester: Heywood and Son, 1899.)

This is a reprint of a lecture delivered in the Chadwick Museum, apparently under the auspices of the Bolton Corporation. It is full of obvious inaccuracies, is hopelessly out of date, and contains on nearly every page cheap sneers at "pure science" and "the scientists," as opposed to the "business" and "practical men." There is a good deal about "Dame Nature" and "Old Ocean," and "the Great Author of the Universe," with whom the author of the book seems to be on curiously confidential terms. This is a work which, if taken seriously, is calculated, we fear, to do much harm—not to the County Council against whose labours it is directed, but to the fishermen in whose interests it professes to be written—by stirring up bad feeling, class prejudices, and opposition to constituted authority.

*A Country Schoolmaster, James Shaw, of Tynron, Dumfriesshire.* Edited by Robert Wallace. Pp. xcvi + 392. (Edinburgh: Oliver and Boyd. London: Simpkin, Marshall, and Co., Ltd., 1899.)

We have first a sketch of the life and work of James Shaw; but the bulk of the book is occupied with reprints of some of his more characteristic literary productions. These are upon a great variety of subjects, mostly connected with natural history. The early years of James Shaw's life were spent as a pattern designer and calico printer, and it was not till he was over thirty years of age that he became the schoolmaster at Tynron, a country parish in Dumfriesshire. He continued there for thirty-four years. In the early part of his career his tastes were chiefly literary, and he acquired considerable power as a writer both of prose and verse. After he became a country schoolmaster he devoted himself entirely to natural history and archæology. His papers collected in the present volume are of real interest, and charmingly written. After looking through them we feel the justice of his friend's remark: "Shaw was a large man, fated to play out his life-drama on a small and dimly-lighted stage."

## LETTER TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* Nature. *No notice is taken of anonymous communications.*]

### Apparent Dark Lightning Flashes.

Last night during a thunderstorm of rare severity in which brilliant flashes—single, double, triple, or quadruple—followed one another at intervals often of not more than a few seconds of time, I was surprised to see with great vividness, on a suddenly illuminated sky, two nearly vertical lines of darkness, each of the ordinary jagged appearance of a bright flash of lightning. I remembered to have seen two real flashes of just the same shapes and relative positions, and I concluded that the black flashes were due to their residual influence on the retina. I turned my eyes quickly from the dark sky outside to an illuminated wall inside the house, and I again saw the same double dark "flash," which verified my conclusion in an interesting manner. The fatigued part of the eye failed to perceive the sudden brightness of the sky in the one case and of the wall in the other.

Aix-les-Bains, August 7. Kelvin.

## MEETING OF THE BRITISH MEDICAL ASSOCIATION AT PORTSMOUTH.

A goodly number of members of this pre-eminently practical Association journeyed last week to Portsmouth to be present at the sixty-seventh annual meeting. The place of meeting was not so attractive as last year, and perhaps on this account the attendance was somewhat smaller. The subject-matter, however, at Portsmouth was quite as interesting as that at Edinburgh; and those who, braving almost tropical heat, were diligent in their attendance at the meetings got their reward, and will return home with ample food for thought.

After an eloquent and interesting address from the President, Dr. Ward Cousins, in which a sketch was given of the progress made in medicine and surgery during the present century, the meeting divided itself up into sections, and settled down to work.

*Section of Medicine.*—An address on medicine was delivered by Sir Richard Douglas Powell, his subject being recent advances in practical medicine. Under this heading various points of practical interest were discussed. The use of the binaural stethoscope received some attention, the author somewhat deploring the decadence of the old rigid stethoscope, a flexible instrument being incapable of transmitting tactile impulses. Under the head of "Anomalous Fevers," Sir Richard discussed shortly the important subject of mixed infection. The value of what was said on serum therapy was enhanced by the addition of a table indicating the actions of the various sera. Under the "Prevention and Treatment of Tuberculosis" the vexed question of the influence of heredity was considered, the author apparently attaching more importance to this influence than recent investigations would seem to justify. The address concluded with a few suggestive hints concerning a possible preparasitic existence of the tubercle bacillus.

At the opening of the section, the President, Dr. Mitchell Bruce, made a few introductory remarks with regard to the subjects of discussion, viz. the tests for admission into the public services, and Tuberculosis. Sir Dyce Duckworth's paper upon the former subject, in his unavoidable absence, was read by the President. The paper comprised a valuable critique of the methods of examination at present adopted by the public services, and a consideration of the causes and rejection of defective candidates. An animated discussion followed this paper. Prof. Osler advocated that the physical examination of candidates should take place earlier in the course of their training, and alluded to the more common causes of, according to him, unnecessary

rejection. Dr. Wallace discussed the matter from a civil standpoint, and advised the forming of a definite standard of physical fitness. Dr. W. Turner drew attention to the mental condition of candidates, and to the not uncommon occurrence of insanity during active service. The result of the discussion was that the following resolutions were sent up to the Council with a request that they be submitted to the War Office: (1) That the physical examination should precede the educational; (2) that soldiers should not serve in the tropics till twenty-two; (3) that the question of the physical standard should receive reconsideration.

A number of papers, which provoked some discussion, upon the ever-present subject of uric acid and gout followed.

*Section of Surgery.*—An address in surgery was delivered by Dr. Ogston, the medical services of the army and navy forming the subject. The author dealt at length with the unsatisfactory condition of the services, both from the point of view of the medical man and the soldier. During the last three decades the class of medical man aspiring to enter the services has very much depreciated, a fact greatly to be deplored. Further, the medical services are undermanned, and there is a want of adequate training. The Indian Medical Service is, to some extent, an exception, and offers many more advantages than the army and navy. The author indicated generally some lines of remedy for the present regrettable condition of the medical services, and contrasted the methods used by the authorities here with those used abroad, notably in Germany, Russia and France.

The president of the section, Mr. Butlin, delivered a short address on the work of the section. The two special subjects for discussion in this section were (1) the diagnosis and treatment of gunshot wounds of the abdomen, and (2) the prevention and treatment of syphilis in the army and navy.

*Section of Obstetrics and Gynaecology.*—The President of this section, Dr. Granville Bantock, delivered an address in which he urged that in gynæcological cases a more conservative attitude might be adopted, and that a diminution in the number of operations performed might with benefit to the patients take place.

An interesting discussion subsequently took place upon fever following delivery, with special reference to serum therapy. The discussion was opened with a paper by Dr. Herbert Spencer. With regard to the serum treatment the author remarked that a large number of observations had now been made upon this subject, 350 cases having been collected by a committee of the American Gynæcological Society. Among these cases there was a mortality of 33 per cent., but the natural mortality of the diseases was probably not greater than this. Little more can be said for this treatment in this class of case than that it somewhat ameliorates the severity of the disease.

*Section of State Medicine.*—Dr. George Wilson delivered the presidential address in this section. The author discussed the relation of bacteriological research and methods to preventive medicine.

*Section of Psychology.*—Dr. Nicolson dealt with the interesting question of the reproachable differences of medical opinion in lunacy cases, and whether they could be avoided. Differences of opinion among medical men were not uncommon in (1) ordinary lunacy cases, (2) civil cases, (3) non-capital criminal cases, and (4) capital criminal cases. In the case of criminal cases, malingering formed a most puzzling element. The author laid stress upon the fact that, although anthropological measurements afforded very valuable information and were to be encouraged as likely in the future to be capable of formulating rules of value, too much stress with regard to individual cases should not be placed upon them. An active discussion followed this paper.

*Section of Anatomy and Physiology.*—The presidential address in this section was delivered by Dr. Charles. The lecturer dealt with the advancement which had recently been made in physiology. He noticed with pleasure that now in this country physiology numbered amongst her votaries a number of accomplished organisers and able laboratory workers, and that we had not now to reproach ourselves with neglecting what Du Bois Reymond rightly called the queen of the natural sciences.

Mr. Stanley Boyd read a paper on the interaction between the ovaries and the mammary glands. This interaction, he remarked, in the cases of removal of both ovaries caused an apparent subsidence and retrogression of cancerous growths in the breast.

*Section of Pathology.*—Dr. Payne delivered the presidential address in this section. A discussion followed upon ulcerative endocarditis.

*Section of Pharmacology and Therapeutics.*—The President, Dr. Bradbury, in opening the work of this section, referred to the difficulty in fixing the place of pharmacology in the medical curriculum. He considered an accurate knowledge of pharmacology to be essential to the practitioner of medicine.

The work of the section began with a paper by Dr. Lauder Brunton on headaches. The paper contained a mass of valuable and interesting information, and comprised a consideration of the *rôle* played by vaso-motor changes in the causation of headaches, and also that played by toxæmic conditions and errors of refraction. The treatments of the different forms of headache were considered, and many useful hints as regards their prevention were given. A discussion followed. Upon replying, Dr. Brunton mentioned that altitudes and depths probably produced headaches by altering the atmospheric pressure in the sinuses.

*Section of Laryngology and Otology.*—The President, Mr. Creswell Baber, delivered an address on the progress of rhinology during the last thirty years.

The section of Tropical Diseases was well attended. Dr. George Thin gave an able address, in which he referred to recent researches on the extra corporeal life of the malarial parasites. The President, after having regretted the unavoidable absence of Major Ross, began to discuss the teaching of tropical medicine. The author dwelt at some length upon the advantages of Netley as affording more material than any other institution for the teaching of tropical medicine, and showed diagrams comparing Netley with London and Liverpool as regards the number of patients available for instruction. According to the author, the advantages possessed by Netley were very great, especially with regard to hepatitis and hepatic abscess.

The museum of the Association, always a prominent feature of the annual meetings, was well filled with exhibits, and was much patronised by members.

*Nunquam animus motu vacuus est.* Absolute rest is a myth of the consulting room often prescribed but rarely practised. It, along with the Salisbury diet and other things, is what one expects of one's friends but not of oneself. The hard-working medical man doubtless wants absolute rest badly enough, but by prefixing his holiday with an attendance at the annual British Medical Association meeting he acts wisely. There work is so mixed up with pleasure that one passes almost insensibly from the one to the other, the meetings forming as it were an intermediate region between work and holiday, shading off the contrast between the two, making the loss of constant occupation less acute, and helping one to slip easily into the *dolce far niente* which one has earned so well.

F. W. TUNNICLIFFE.

## THE RELATION OF MOTION IN ANIMALS AND PLANTS TO THE ELECTRICAL PHENOMENA ASSOCIATED WITH IT.[1]

THE lecturer began by observing that the proper subject of the lecture being "the nature or laws of muscular motion,"[2] he would discuss the chemical, mechanical and electrical concomitants of this most important function with a view to the elucidation of their mutual causal relations. He would, however, ask the attention of the Society chiefly to the *electrical* phenomena which are associated with muscular action, as being those which he had himself specially studied. Some points relating to the *mechanical* effects of muscular action must be referred to by way of introduction, inasmuch as it is by these that a muscle performs its function as an organ of motion. There were two ways of investigating these effects experimentally. We might observe and record either the change of form which a muscle undergoes in response to a stimulus of very short duration when contracting isotonically, *i.e.* as it does when lifting a weight, or the increase of tension which occurs when it endeavours to overcome a resistance, *i.e.* when it acts isometrically. It was shown that although, as regards an entire muscle, the isometric method was preferable to the isotonic, the time occupied by a single element of muscular structure when directly excited in developing its maximum tension (*i.e.* in the transformation of chemical into mechanical energy) could be best estimated under isotonic conditions. He then proceeded to describe his own method of accomplishing this measurement with the aid of photography. It consists in observing the change of form of the surface of a living muscle when a single break induction current is led through it in such a way that the observed surface is at the kathode. A magnified image of the kathodic electrode, which moves freely with the muscle, is projected on a slit behind which a sensitive plate passes, and in this way a curve is obtained from which the time-relations of the movement can be deduced. It is thus learned that at the kathodic spot, *i.e.* at the spot immediately excited, the process attains its greatest activity before the end of the first hundredth of a second. The importance of this datum consists in its bearing on the question whether or not the electrical change by which the change of form thus observed is accompanied is coincident with it, follows or precedes it. The answer to this question could not, of course, be given until the time-relations of the electrical change had been considered. These were discussed as follows:—

The essential point in investigating the *electrical* changes which occur in muscle is to connect two parts of its surface through a galvanoscope. The general result of such an exploration is (1) that similar parts in a similar physiological state are equipotential; (2) that between similar parts which are not in the same state there is always a difference of potential, measurable by the method of compensation, the less capable of function, *i.e.* the less living, being negative to the more living; and (3) that transitory differences of potential arise between two parts of the living surface when the one is excited to discharge of function, the other remaining at rest. Thus the state of rest or fitness for function of a part is denoted by relative "positivity," discharge of function by relative "negativity."[3]

[1] Abstract of the Croonian Lecture, delivered before the Royal Society, by J. Burdon-Sanderson, M.A., M.D., F.R.S., on March 16.
[2] See "The Record" of the Royal Society, 1897, p. 126.
[3] The use of these words in the sense above stated has been strongly objected to. It is difficult to see to what obscurity of meaning it can give rise. "Negativity" of a surface means nothing more than it is negative *relatively* to another surface.

*First Fundamental Experiment.*—The effect of an excitation which is instantaneous and so localised as to affect in the first instance only one of the two surfaces of contact is the sudden manifestation of a difference of potential between them, this effect being momentary (case 1) or continuous (case 2) according to the duration of the excitation. In either case it is designated "excitatory variation" if the muscle is referred to, *or* "action current" if the galvanoscope is referred to.[1] If the capillary electrometer is used as galvanoscope, and its excursions are recorded photographically, the curves so obtained truly and faithfully express to us the character and time-relations of the *variation*, provided only that we know according to what rule they are to be interpreted. This rule can be deduced from the well-known properties of the instrument, as has been fully set forth elsewhere.[2] We may, however, interpret the photographic curves we obtain in the exploration of living muscle by *comparing* them with counterparts photographed under previously determined and known physical conditions. Thus by arranging our physical experiment so as to reproduce the hypothetical conditions of our physiological one, we may prove the truth of our hypothesis by the coincidence of the two results. And inasmuch as the two cases, *i.e.* the two forms of "variation," above referred to, are the only ones that present themselves, provided that we adopt a mode of procedure to be presently explained, there is no difficulty in applying this purely empirical procedure.

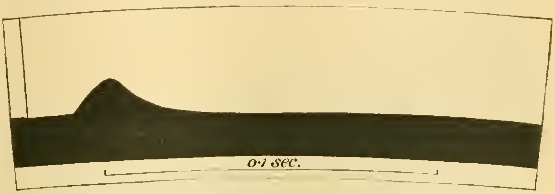

FIG. 1.—Photographic curve of diphasic variation of sartorius muscle. Rate of movement of plate indicated by distance accomplished in 1/10 sec.; moment of excitation by vertical (radial) line.

The first fundamental experiment is one in which a curarised muscle of simple structure (*i.e.* one which consists of a band of parallel fibres) is subjected to the action of an instantaneous stimulus applied to it near one end, as shown below. The result is that a wave of excitation,

of which the progress is marked by mechanical and electrical changes, passes along each fibre (represented by the black line), starting from the seat of excitation $r$, and affecting first the nearest contact $p$, and after an interval the more distant contact $d$. The photograph (Fig. 1) is the curve obtained under these conditions. But if, as above suggested, we proceed in such a way as to limit the observation to what happens at one contact only, and for this purpose *cancel* the effect at the further contact $d$, and repeat our photographic observation just as before, we find that the curve has assumed an entirely different form shown in the photograph (Fig. 2). [As in both photographs, the movement of the sensitive plate is circular, the ordinates are polar, and must be measured accordingly.] Before the effect at $d$ was cancelled, the curve had the form shown in Fig. 1. We therefore conjecture that the

[1] Here again our language has been objected to. "Excitatory variation" means the coming into existence of a difference of potential between two surfaces in consequence of stimulation of one or both of them. It is a translation of the German word "Reizschwankung."
[2] *Journal of Physiology*, xxiii. p. 325.

difference of contour between Figs. 1 and 2 represents the effect of the arrival of the wave of excitation at the distal electrode *d*. The proof that this is so is as follows (see diagram, Fig. 3):—From the measurement of the polar ordinates of Fig. 1 we obtain by calculation the curve P′, which represents the change which occurs in the

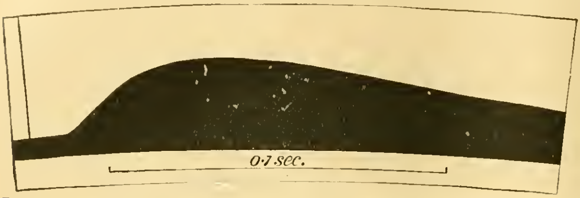

FIG. 2.—The same as Fig. 1 after cancelling the excitatory change at D. (See diagram on p. 343.)

difference of potential between the surface of contact *p* and the rest of the surface of the muscle during the period of excitation.[1] We assume an identical curve D′ in the same relation to the contact *d*, differing from P′ only in the opposite sign of its ordinates, and relating to a period a little (in the case represented 15/1000 sec.) later than of P′; and by summing the synchronous ordinates of the two curves P′ and D′ algebraically, we obtain the curve S′, which expresses what must be the successive differences of potential between *p* and *d* when the effect of the change at *d is not cancelled*. If we deduce this curve by calculation from Fig. 2, the two curves, *i.e.* the deduced curve and the summation curve, ought to coincide. Their actual coincidence shows that the relation between the curves P′, D′ and S′ has been correctly understood; it affords satisfactory proof that from P′ we can deduce S′, and consequently good reason for making the determination of P′, *i.e.* the *monophasic variation*, the aim of our experimental method.

With reference to this method there are two points still to be adverted to. One is that it gives us the means of measuring with great exactitude the rate of propagation of the "excitatory wave," the progress of which from the seat of excitation has been already mentioned, and of proving that, although it varies according to the temperature and the vitality of the muscle, it is, under unchanging conditions, fairly constant. The other point relates to the mode of cancelling the effect of the wave of excitation at the distal electrode. The most effectual and simplest way of doing this is to apply a tight ligature across the path of propagation, the effect of which is to arrest the progress of the wave in its course from *p* to *d*. Another method is to devitalise the part of the muscle to which the distal electrode is applied by heat. The result in the two cases is the same as regards the electrical response to excitation. Fig. 1 is converted into Fig. 2. But as regards the electrical state of the muscle when at rest it is different—*i.e.* when the ligature is applied half-way between *p* and *d* the contacts remain equipotential, or nearly so; whereas in the other case the unexcited and unexcitable dead surface is found to be strongly negative to the other.

We are now in a position to sum up what is to be learned from the first fundamental experiment. The most important result is that, both as regards the muscle when "at rest" and the change of state which is evoked by excitation, the observed instrumental effect depends exclusively on the state of the surfaces of contact, and consequently, when the distal contact is cancelled, on that of the proximal contact only.

*Second Fundamental Experiment.*—We have so far only considered experimentally the effects of a single instantaneous excitation on muscle, causing it to give the mechanical effect known as a twitch. We have now to inquire what are the electrical concomitants of *continuous contraction*. This part of the subject has greater interest than the one we have been considering, inasmuch as it involves the question of the nature of ordinary voluntary muscular action, with reference to which there are reasons for holding that its continuity is apparent only. One of the chief of such reasons is to be found in the supposed resemblance of the sound of a muscle contracting normally to the musical sound of a muscle subjected to a rapid series of instantaneous stimuli. It is ordinarily stated that inasmuch as we can produce continuous contraction by discontinuous stimulation (artificial tetanus), all continuous contraction is so produced. Putting aside the question of muscle-sound, which does not here concern us, and confining ourselves to the electrical concomitants of continuous action, it can be shown that under certain conditions a continuous effect can be evoked by a single uninterrupted stimulus, and that in the nearest approach we can get to natural contraction, the reflex spasm, there is no evidence of discontinuity *in the sense in which this is usually understood*. Let us first see what are the electrical concomitants of artificial tetanus. If the muscle is completely tetanised, *i.e.* subjected to a succession of stimuli at the rate of over 50 per second, the electrometer gives us a curve, of which the general form is shown in Fig. 4. The muscle passes at once from the state of *capacity for action* into the state of *action*. This is indicated by the sudden manifestation of a difference of potential, which persists as long as its cause.

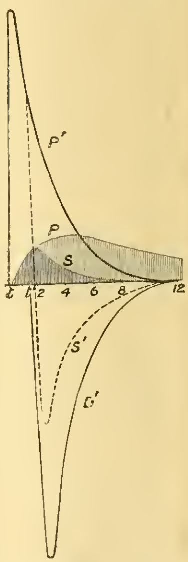

FIG. 3.—Diagram showing the relation between the photographic curves and the curves of difference of potential which they indicate and between the monophasic curves P′ and D′ and the diphasic S′. The numbers below the horizontal line denote hundredths of a second.

When the rate of excitation is less frequent, the electrometer curve gives evidence that the tetanus, whether still mechanically complete, or already incomplete, is composed of a series of twitches, *i.e.* of single monophasic effects. [Photographs were shown of the response in a sartorius, devitalised under the distal electrode, and excited by a series of instantaneous stimuli following each other with a frequency of 60 per sec. in one case, 20 per sec. in the other.]

If, however, while still retaining the higher frequency, we subject the muscle to a series of short tetanising excitations, each lasting say for a tenth of a second or more, and succeeded by a rest of similar duration, we obtain a curve of alternate polarisation and depolarisation such as would represent short, but persisting, differences of potential, alternating with periods of indifference (Fig. 5).

[1] The way in which the curve P′ is deduced is fully given in the paper quoted above in the *Journal of Physiology*, vol. xxiii.

*The Reflex Spasm.*—We may now pass to *reflex action*, in which, since the motor apparatus of the cord has to be first excited through a sensory nerve, the time which elapses before a response is evoked is necessarily longer than in the cases we have been so far considering. The

FIG. 4.—The photographic curve of tetanus. The radial indicates the beginning of the period of excitation.

response, if the motor cells of the cord have been rendered extra sensitive by a minute dose of strychnine, is a prolonged contraction [tracing of mechanical effect shown] the graphic of which is often indistinguishable from that of complete tetanus. When the electrical concomitants of such a spasm are recorded photographically (Fig. 6), it is seen that the curve resembles rather that of complete tetanus interrupted at regular intervals, than that of a series of responses to single instantaneous stimuli following each other at intervals of a tenth of a second or more. And by analysing the curve we learn that the difference which in the first instance comes into existence between the contacts, disappears and reappears rhythmically, and finally ceases. A single stimulus to the motor cells of the cord has therefore produced a series of short prolonged responses in the muscle, of which the rhythm is *central*, not muscular. The motor cell pours its influence on the muscle at regular intervals, but its effect each time is that of a continuous action.

The property which a muscle has of, under ordinary experimental conditions, relaxing as soon as the exciting

FIG. 5.—Tetanus of short duration, followed by another after an interval during which the muscle was not excited.

cause ceases, appears at first to indicate discontinuity of voluntary action. We have, however, a means of removing this property without materially impairing the functional capacity of the muscle. This means is furnished by the alkaloid *veratrine*. So long as this is used in sufficiently small quantity ($\frac{1}{10000}$ mgr. to a sartorius), its effect consists chiefly in the annulling of the unknown inhibitory mechanism, by virtue of which a muscle, after having responded to an instantaneous stimulus, at once returns to its previous state. Under the influence of veratrine, when once started to work it is compelled to go on. [It was shown by graphic records that a muscle so treated can do as much work in response to a single instantaneous stimulus, whether in lifting heavy loads or in producing tension, as a normal muscle subjected to a series of instantaneous stimuli.] The electrical phenomena evoked by a single stimulus in a veratrinised muscle likewise show that the effect is absolutely continuous; there is no trace of unevenness or undulation in the photographic curve (Fig. 7), the contour of which resembles the general contour of artificial tetanus, *i.e.* a sudden difference of potential comes into existence at the moment of excitation, but, notwithstanding that it is evoked by an instantaneous stimulus, it persists as if it were the response to a continuous one.

FIG. 6.—Reflex response of sartorius to instantaneous excitation in strychnised preparation.

To complete the subject, it is necessary to describe the electrical phenomena which accompany the action of the heart. In all that has preceded, a parallel-fibred muscle has been employed in which the excitatory wave is propagated along the fibres in two opposite directions only. In the heart the fibres are short, and run in all directions. The wave of excitation may originate anywhere, and may spread in any direction. We employ the ventricle of the heart of the frog, having first arrested its rhythmical beat by a ligature between sinus and auricle. We can then evoke a contraction by an instantaneous excitation at any part of its surface, and thus imitate the first fundamental experiment in muscle. At the excited point the surface becomes instantly negative to all other parts, and the state of relative negativity spreads radially just as in muscle it was propagated longitudinally, the electrical effect appearing to precede the mechanical. Moreover, the duration of the process is ten times as long, and the rate of propagation ten times as slow. But in other respects the two processes in cardiac and skeletal muscle

are so analogous, that if the distance of the contacts, the duration of the change at the seat of excitation (monophasic variation), and the rate of propagation are known, it is easy to forecast the curve of the diphasic variation.

By a similar method to that employed in the study of muscle, the effect at the distal contact can be partially or entirely cancelled. All that is necessary is to destroy by heat the surface under the distal electrode. The result of this operation is that, as in muscle, the devitalised area becomes, while unexcited, negative to all uninjured parts, and that if the surface is excited in the neighbourhood of the uninjured contact, the photographic curve assumes characters which correspond with those of the monophasic curve of muscle, with this noteworthy difference that its duration is that of the ventricular beat.

FIG. 7.—Response of veratrinised muscle to instantaneous stimulation.

This can be best understood from the photographic curves reproduced in Fig. 8, with reference to which it is to be noted that the rate of movement of the plate on which the movement of the mercury column is projected is *ten times* as slow as the slowest rate of movement used in observations of muscle. Had the excursion been projected on a plate moving at the same rate, the first half of the curve would have had a contour similar to the veratrine curve. It expresses a sudden coming into existence of a difference of potential between the two contacts which may be maintained (in the heart) for more than two seconds.

In the second curve of Fig. 8 the curve begins as in the first, but the effect on the electrometer of the change which is taking place at the proximal electrode is immediately afterwards counteracted and balanced by the similar change at the distal contact, and is followed by a period of indifference, the end of which is marked by a descent of the column. This (as was explained by the lecturer many years ago) means that the effect at the distal electrode over-lasts that which occurs at the proximal.

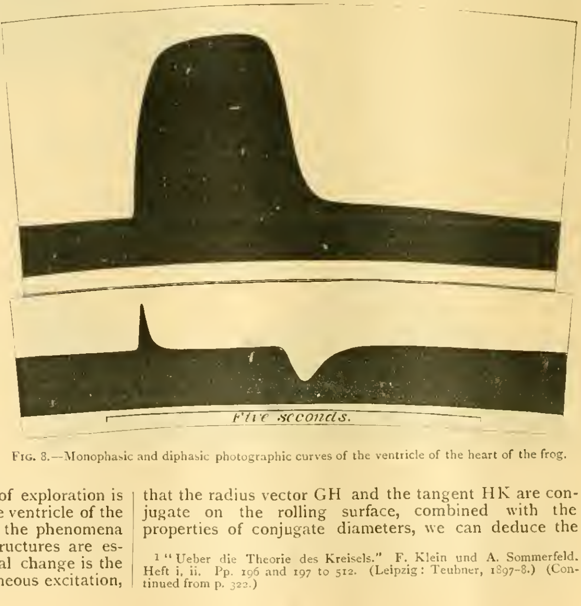

FIG. 8.—Monophasic and diphasic photographic curves of the ventricle of the heart of the frog.

The lecture concluded with a comparison of the electromotive properties of the leaf of the fly-trap with those of muscle. If the same method of exploration is applied to the surface of the leaf as to the ventricle of the heart of the frog, it is easy to show that the phenomena observed after excitation in the two structures are essentially analogous. In both an electrical change is the immediate result of a localised instantaneous excitation, and this change spreads from the excited spot to parts at a distance at a rate which varies with temperature. The interval of time between the culmination of the electrical response and that of the change of form is much more obvious in the leaf than in the heart, because the mechanism by which the latter manifests itself works very slowly, as compared even with cardiac muscular fibres. This contrast, however, affords no ground for doubting that the two processes are, as regards their intimate nature, analogous.

## *MATHEMATICS OF THE SPINNING-TOP.*[1]

### II.

IT is instructive at this stage to go behind the various relations given by Darboux and Routh, connecting A, B, C, D, and $\delta$, and the accented letters, and to examine their inner geometrical significance; various interesting theorems of Geometrical Conic Sections will be required, which will show the practical utility of the study of this elegant subject, as presented in Taylor's "Geometry of Conics."

In the first place we can connect up the notation of Darboux and Routh by taking

$$(28)\quad \frac{a,\ b,\ c,\ h}{m} = \frac{\text{HV, HT, HP, HQ}}{\text{OD}} = \left(\frac{\text{D}}{\text{A}},\ \frac{\text{D}}{\text{B}},\ \frac{\text{D}}{\text{C}},\ 1\right)\frac{\text{HQ}}{\text{OD}},$$

Darboux's $a$, $b$, $c$, $h$ being of the same dimensions as $m$, an angular velocity estimated in radians/second.

From the fundamental property of the herpolhode as the trace of the points of contact of a quadric surface, rolling about its centre O on a fixed plane GH, namely, that the radius vector GH and the tangent HK are conjugate on the rolling surface, combined with the properties of conjugate diameters, we can deduce the

[1] "Ueber die Theorie des Kreisels." F. Klein und A. Sommerfeld. Heft i, ii. Pp. 196 and 197 to 512. (Leipzig: Teubner, 1897-8.) (Continued from p. 322.)

analytical theorems of the curve. Thus, if OE and OF are the conjugate diameters parallel to the tangent HK and the vector GH, and if OK is the perpendicular on HK, then, with Darboux's notation,

$$a+b+c=\mathrm{P},\ bc+ca+ab=\mathrm{Q},\ abc=\mathrm{R},$$

and putting

$$\frac{\mathrm{OG}^2}{\mathrm{OD}^2}=\frac{h}{m},$$

$$(29)\qquad \frac{\mathrm{OE}^2+\mathrm{OF}^2+\mathrm{OH}^2}{\mathrm{OD}^2}=\frac{\mathrm{P}}{m},$$

$$(30)\qquad \frac{\mathrm{OE}^2 . \mathrm{OF}^2 \sin^2 \mathrm{EOF}+\mathrm{OK}^2 . \mathrm{OE}^2+\mathrm{OF}^2 \quad \mathrm{OG}^2}{\mathrm{OD}^4}=\frac{\mathrm{Q}}{m^2},$$

$$(31)\qquad \frac{\mathrm{OG}^2 . \mathrm{OE}^2 . \mathrm{OF}^2 \sin^2 \mathrm{EOF}}{\mathrm{OD}^6}=\frac{\mathrm{R}}{m^3}.$$

The elimination of $\mathrm{OE}^2$, $\mathrm{OF}^2$, and $\sin^2 \mathrm{EOF}$ between these equations gives the relation connecting $\mathrm{OH}^2$ and $\mathrm{OK}^2$ in the herpolhode; it is linear in $\mathrm{OK}^2$ and quadratic in $\mathrm{OH}^2$. The geodetic radius of curvature of the polhode on the polhode cone is readily found by a differentiation by exactly the same formula as the *rdr dp* formula of a plane curve; and the radius of curvature of the herpolhode in the plane of G is the projection of this geodetic radius of curvature.

At a point of inflexion on the herpolhode this geodetic radius of curvature is infinite, and now the polhode is a bit of a geodesic on the polhode cone; this shows that the osculating plane of the polhode is now perpendicular to OK.

But to find whether the herpolhode can have points of inflexion, we merely require to find where the value of OK is stationary, and this is found by solving the quadratic in $\mathrm{OH}^2$, and examining its discriminant; in this way we shall find that the discriminant vanishes, and OK is at a turning point, when

$$(32)\qquad m\frac{\mathrm{GK}^2}{\mathrm{OD}^2}=0,\ \text{ or }\ \frac{4(a-h)(b-h)(c-h)\mathrm{R}}{\Omega^2 h},$$

where, in Darboux's notation,

$$\Omega^2=\mathrm{Q}^2-4\mathrm{R}(\mathrm{P}-h).$$

The value GK = 0 is excluded when the rolling surface is an ellipsoid; it will be found that the other value makes

$$m\frac{\mathrm{OF}^2}{\mathrm{OD}^2}=\frac{\mathrm{Q}}{2h},$$

$$m^2\frac{\mathrm{OF}^2 . \mathrm{OG}^2}{\mathrm{OD}^4}=\tfrac{1}{2}\mathrm{Q};$$

and the maximum value of this being $ab$, it follows that

$$ab-\tfrac{1}{2}\mathrm{Q}=\tfrac{1}{2}\mathrm{R}\left(\frac{1}{c}-\frac{1}{a}-\frac{1}{b}\right)=\frac{1}{2}m^2\frac{\mathrm{HQ}^2}{\mathrm{OD}^2}\frac{\mathrm{D}^2}{\mathrm{ABC}}(\mathrm{C}-\mathrm{A}-\mathrm{B})$$

is positive, so that the rolling quadric cannot be the momental ellipsoid of real positive matter for points of inflexion to exist, in accordance with the theorems of Hess and de Sparre.

Fig. 1 has been drawn with the idea at first of giving the graphical representation of the numerical case discussed in VI. § 6; so that

$$f=\frac{a-b}{\omega'}=-0{\cdot}0068,\quad f'=\frac{a+b}{\omega'}=1{\cdot}421$$

(these numbers appear to show that $s$ and $s'$ on p. 481 must be interchanged).

But as these numbers bring the point P inconveniently near to A, fresh dimensions are chosen; we can take a scale such that OA = 10 cm., OB = 5, so that $\kappa$ is reduced from 0·521 to 0·5; and the points P and P′ were so placed as to make $\theta_3 = 45°$, $\theta_2 = 30°$; and now, by measurement, OD = 17·73 cm.,

| | |
|---|---|
| HQ = 16·4 cm. | HQ′ = 8·9 cm. |
| HT = 5·4 cm. | HT′ = 21·6 cm. |
| HV = 15·0 cm. | HV′ = 8·3 cm. |
| HP = 6·2 cm. | HP′ = 10·4 cm. |

The angle AOQ or $\omega = 33°$ by measurement, so that from Legendre's Table IX., to the co-modular angle 60°,

$$\mathrm{F}\omega=0{\cdot}6009,\quad \mathrm{K}'=2{\cdot}1565,$$
$$\mathrm{E}\omega=0{\cdot}5528,\quad \mathrm{E}'=1{\cdot}2111;$$

and thence

$$f=-0{\cdot}2787,$$

and

$$\mathrm{QL}=2{\cdot}153\ \text{cm}.$$

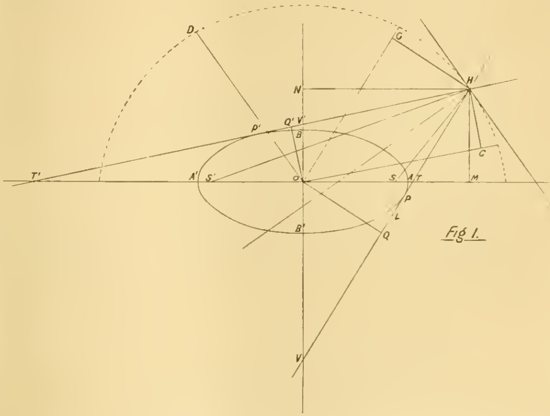

Fig. 1.

Thence the apsidal angle, as a fraction of a right angle, is given by

$$(33)\qquad \frac{\Psi}{\frac{1}{2}\pi}=\frac{\mathrm{HL}}{\mathrm{OA}}\frac{\mathrm{K}}{\frac{1}{2}\pi}+f=1{\cdot}245.$$

As $\theta$ diminishes from $\theta_3$ to $\theta_2$, the deformable hyperboloid opens out from the plane of the focal ellipse and flattens again in the plane of the focal hyperbola. As a typical intermediate position choose that of half-time; with our dimensions this will make

$$\sin^2\phi=\frac{1}{1+\kappa'}=0{\cdot}5359,$$

$$\cos\theta=0{\cdot}792,\ \theta=37°\ 37'.$$

Project the figure on to the plane of the generating lines HQ, HQ′, which are now drawn inclined at 37° 37′, and place the points Q, T, V, P, &c., on these lines as before; the confocal quadrics project into confocal conics.

The lines TT′, VV′, PP′ form a triangle XYZ, the sides of which are the traces of the principal planes: $\Omega$, the orthocentre of this triangle, is the projection of the origin O.

We must be content with the mere statement of the following geometrical theorems, required for throwing light upon the analytical theorems of this dynamical problem, with a view of obtaining a clear image of the motion in accordance with Poinsot's ideas; the demonstrations will be found in Salmon's "Solid Geometry,"

or better still, in Mannheim's "Géométrie Cinématique," which has been found valuable in carrying on the Poinsot traditions of dynamical presentation.

Join HΩ, cutting the sides of the triangle XYZ in $\alpha, \beta, \gamma$; describe the circle round XYZ, and let XΩ, YΩ, ZΩ cut this circle in $d, e, f$; then $\alpha d$, $\beta e$, $\gamma f$ intersect the circle in one point F. F is the focus, and HΩ the directrix of the parabola, which is the envelop of the normals of the confocals (Salmon, "Solid Geometry," § 177); this parabola touches the sides of the triangle XYZ; the tangents to the parabola from H are tangents to the projections on the plane of the confocals through H, while the tangents to the parabola from Ω are the axes of these plane confocals; also HΩ and HF are equally inclined to HQ and HQ'.

If H$c$, H$c'$ are the tangents to the parabola from H, the points of contact $c$ and $c'$ are the centres of curvature of the plane confocals through H; while C and C', the centres of curvature of the normal sections of the confocal surfaces through H made by planes through the line of curvature traced out H, are such that

$$\mathrm{HC} = \mathrm{H}c \cos^2 \tfrac{1}{2}\theta, \quad \mathrm{HC}' = \mathrm{H}c' \sin^2 \tfrac{1}{2}\theta,$$

and thus the point C and C' are easily constructed geometrically.

The line CC (a tangent to the parabola) is Mannheim's *axis of curvature*, and the plane through H perpendicular to it is the osculating plane of the polhode. Thus in the degenerate case of Fig. 1, when H lies in the plane of the focal ellipse, PP' is the axis of curvature of the polhode, while Z and Ω coincide with O.

The various relations in the conjugate Poinsot movements, investigated by Darboux and Routh, and given in VI. § 8, can now receive a geometrical interpretation.

Thus the relation (2), p. 476, written in the form

$$(34) \qquad \frac{\mathrm{B}}{\mathrm{A}} + \frac{\mathrm{B}'}{\mathrm{A}'} = \frac{\mathrm{C}}{\mathrm{A}} + \frac{\mathrm{C}'}{\mathrm{A}'}, \text{ \&c.},$$

is the equivalent of

$$(35) \qquad \frac{\mathrm{HV}}{\mathrm{HT}} + \frac{\mathrm{HV}'}{\mathrm{HT}'} = \frac{\mathrm{HV}}{\mathrm{HP}} + \frac{\mathrm{HV}'}{\mathrm{HP}'}, \text{ \&c.};$$

expressing the fact that, if PP' cuts OA in X in Fig. 1, then MX is the harmonic mean of HT, HT' and of H$m$, H$m'$, where $m$, $m'$ are the feet of the ordinates from P, P' on OA.

Again, if XΩ meets YZ in D, then OD and OV are conjugate diameters in the principal plane OYZ of the rolling quadric

$$(36) \qquad \frac{x^2}{\mathrm{HV}} + \frac{y^2}{\mathrm{HT}} + \frac{z^2}{\mathrm{HP}} = \mathrm{HQ},$$

and therefore

$$\frac{\mathrm{HP}}{\mathrm{HT}} = \tan \mathrm{YOD} \tan \mathrm{YOV} = \frac{\mathrm{VY}}{\mathrm{VZ}};$$

similarly

$$\frac{\mathrm{HV}}{\mathrm{HP}} = \frac{\mathrm{TZ}}{\mathrm{TX}}, \quad \frac{\mathrm{HT}}{\mathrm{HV}} = \frac{\mathrm{PX}}{\mathrm{PY}};$$

so that, drawing X$x$ parallel to YZ to meet HQ and HQ' in $x$ and $x'$,

$$\frac{\mathrm{HV}}{\mathrm{HT}} = \frac{\mathrm{PV}}{\mathrm{PX}} = \frac{\mathrm{PV}}{\mathrm{P}x}, \quad \frac{\mathrm{HV}}{\mathrm{VT}} = \frac{\mathrm{PV}}{\mathrm{V}x}.$$

$$(37) \qquad \frac{\mathrm{VP.VT}}{\mathrm{HV}^2} = \frac{\mathrm{V}x}{\mathrm{HV}} = \frac{\mathrm{V}'x'}{\mathrm{HV}'} = \frac{\mathrm{V'P'.V'T'}}{\mathrm{HV}'^2}$$

the geometrical equivalent of the relation

$$(38) \qquad \left(1 - \frac{\mathrm{A}}{\mathrm{B}}\right)\left(1 - \frac{\mathrm{A}}{\mathrm{C}}\right) = \left(1 - \frac{\mathrm{A}'}{\mathrm{B}'}\right)\left(1 - \frac{\mathrm{A}'}{\mathrm{C}'}\right).$$

Similarly for the other relations, which we have not space to develop.

The A and C employed here require to be carefully distinguished from the values referring to the top itself, which ought to be differentiated by a suffix.

The constancy of the perpendicular from the centre on the tangent plane of the rolling quadric along the polhode is expressed by

$$(39) \qquad \frac{x^2}{\mathrm{HV}^2} + \frac{y^2}{\mathrm{HT}^2} + \frac{z^2}{\mathrm{HP}^2} = 1,$$

and

$$\frac{x}{\mathrm{HV}}, \quad \frac{y}{\mathrm{HT}}, \quad \frac{z}{\mathrm{HP}}$$

are obviously the cosines of the angles which the line HQ makes with the coordinate axes.

The Darboux-Kœnig's arrangements by which the polhode, herpolhode, and associated top motion are produced mechanically by articulated movements, are worth mention and study in elucidating the various theorems.

When the parameters $a$ and $b$ (p. 263) are aliquot parts of the period $\omega'$, the multiplicative elliptic functions $\alpha, \beta, \gamma, \delta$ become algebraical functions of $u$, qualified by exponential functions of the time. Take the simplest case, where $a = \frac{1}{2}\omega'$, $b = \frac{1}{2}\omega'$, equivalent to placing P at A and P' at B in Fig. 1, then we shall have

$$e = 0, \quad e' = \kappa, \quad e'' = \frac{1}{\kappa};$$

$$\alpha = \frac{1}{\sqrt{2}} e^{lti}\left[\sqrt{(e'' - u \,.\, e' - u)} + i\frac{1+\kappa}{\sqrt{\kappa}}\sqrt{(u - e)}\right]^{\frac{1}{2}},$$

$$\beta = \frac{1}{\sqrt{2}} e^{l'ti}\left[\sqrt{(e'' - u \,.\, e' - u)} - i\frac{1-\kappa}{\sqrt{\kappa}}\sqrt{(u - e)}\right]^{\frac{1}{2}}, \text{ \&c.},$$

with

$$l = \frac{1+\kappa}{4\sqrt{2\kappa}} m + \tfrac{1}{2}\left(\frac{1}{\mathrm{C}} - \frac{1}{\mathrm{A}}\right)\mathrm{N},$$

$$l' = \frac{1-\kappa}{4\sqrt{2\kappa}} m - \tfrac{1}{2}\left(\frac{1}{\mathrm{C}} - \frac{1}{\mathrm{A}}\right)\mathrm{N},$$

$$\tfrac{1}{2} i \sin \theta e^{\psi i} = \alpha\beta = \tfrac{1}{2} e^{(l+l')ti}\left[\sqrt{(1 - \kappa u)} + i\sqrt{(u \,.\, \kappa - u)}\right].$$

In the next case, where

$$a = \tfrac{2}{3}\omega', \quad b = \tfrac{1}{3}\omega',$$

it is found that we can put

$$e = -1 + c, \quad e' = -\frac{1 - 3c + c^2}{(1-c)^2}, \quad e'' = \frac{1-c}{c};$$

$$\alpha = \frac{1}{\sqrt{2}} e^{lti}\left[\frac{(1 - c + c^2)u + (1-c)^2}{(1-c)\sqrt{c}} + i\sqrt{\mathrm{V}}\right]^{\frac{1}{3}}$$

$$\beta = \frac{1}{\sqrt{2}} e^{l'ti}\left[\frac{(1-2c)(2-c)}{(1-c)\sqrt{c}}\sqrt{(e'' - u \,.\, u - e)} + i\left\{u - 2\frac{(1-c)^2}{c}\right\}\sqrt{(e' - u)}\right]^{\frac{1}{3}}, \text{ \&c.}$$

with

$$l = \tfrac{1}{3}\frac{1 - c + c^2}{(1-c)\sqrt{2c}} m + \tfrac{1}{2}\left(\frac{1}{\mathrm{C}} - \frac{1}{\mathrm{A}}\right)\mathrm{N}$$

$$l' = -\tfrac{1}{3}\frac{(2-c)(1-2c)}{(1-c)\sqrt{2c}} m - \tfrac{1}{2}\left(\frac{1}{\mathrm{C}} - \frac{1}{\mathrm{A}}\right)\mathrm{N}.$$

The general form of this solution can now be inferred, but it is evident that the algebraical complexity mounts up very rapidly; with

$$a = \frac{2r\omega'}{n}, \quad b = \frac{r\omega'}{n},$$

$$\alpha = \frac{1}{\sqrt{2}} e^{lti}\left[\mathrm{A}_1 + i\mathrm{A}_2\sqrt{\mathrm{V}}\right]^{\frac{1}{n}},$$

$$\beta = \frac{1}{\sqrt{2}} e^{l'ti}\left[\mathrm{B}_1\sqrt{(e'' - u \,.\, u - e)} + i\mathrm{B}_2\sqrt{(e' - u)}\right]^{\frac{1}{n}},$$

where the A's and B's are rational polynominals of $u$.

Thus for $n = 5$, we can take

$$e = -\frac{2c}{\sqrt{\mathrm{C}} + 1}, \quad e' = \frac{c^3 - 3c^2 - c - 1}{4c}, \quad e'' = \frac{2c}{\sqrt{\mathrm{C}} - 1},$$

where

$$\mathrm{C} = c^3 + c^2 - c;$$

and

$$\mathrm{A}_1 = \mathrm{P}u^2 + \mathrm{P}_1 u + \mathrm{P}_2, \quad \mathrm{P} = \frac{c^3 - c^2 + 7c - 3}{2c^{\frac{1}{2}}(c+1)(c-1)^{\frac{1}{2}}},$$

$$P_1 = \frac{5c^5 - 11c^4 + 26c^3 - 10c^2 + c - 1}{2c^{\frac{3}{2}}(c+1)^3(c-1)^{\frac{1}{2}}}, \quad P_2 = \frac{c^4 - 10c^3 + 2c^2 - 2c + 1}{c^{\frac{1}{2}}(c+1)^3(c-1)^{\frac{1}{2}}};$$

$$A_2 = u + \frac{5c^2 - 2c + 1}{c(c+1)^2}, \quad l = \frac{P}{5\sqrt{2}} + \tfrac{1}{2}\left(\frac{1}{C} - \frac{1}{A}\right)N;$$

$$B_1 = Qu + Q_1,$$

where

$$Q = \frac{(c+3)(c^2 - 4c - 1)}{2c^{\frac{1}{2}}(c+1)(c-1)^{\frac{1}{2}}}, \quad l' = \frac{Q}{5\sqrt{2}} - \tfrac{1}{2}\left(\frac{1}{C} - \frac{1}{A}\right)N,$$

$$Q_1 = -\frac{(c^2 - 4c - 1)(5c^2 + 2c + 1)}{2c^{\frac{3}{2}}(c+1)(c-1)^{\frac{3}{2}}}.$$

$$B_2 = u^2 - \frac{5c^3 + 19c^2 + 7c + 1}{c(c+1)^2(c-1)}u + \frac{-2c^3 + 22c^2 + 10c + 2}{(c+1)^2(c-1)^2}.$$

The same functions $\alpha$, $\beta$, $\gamma$, $\delta$, and their special algebraical forms are suitable for Kirchoff's case of the motion of a solid in infinite liquid, but now V is a quartic function of $u$, requiring resolution into factors.

In the more general case invented by Clebsch, and developed in Halphen's "Fonctions elliptiques," t. II., the component rotation about OZ is no longer constant, and the solution is more complicated, introducing multiplicative elliptic functions to a parameter corresponding to the infinite value of $u$.

If the motion of the axis of the top is alone required, we take $\Lambda = \infty$, and investigate the function $\lambda = \alpha\gamma$; this is a multiplicative elliptic function, with an effective parameter $a-b$, which can be made algebraical when $a-b$ is made an aliquot part of $\omega'$, irrespective of the separate terms $a$ and $b$. By a further restriction, the exponential function of the time can be made to disappear by making $l + l' = 0$, and then H is at L in Fig. 1; it was in this way that the analysis was prepared of the algebraical cases, represented stereoscopically by Mr. T. I. Dewar, referred to on p. 199.

The authors say they have refrained from utilising these stereoscopic diagrams, because they would not like to assume in the reader the possession of a stereoscope. But our eyes should be drilled into control to pick up the solid appearance without any apparatus; a little quiet practice will suffice. Treatises on Solid Geometry of the future should be profusely illustrated with stereoscopic figures, which the student should see solid at will; and wall diagrams or lantern projections should also be drawn stereoscopically, and the solid effect obtained in the audience by crossing the two lines of sight.

Mr. T. I. Dewar's untimely death, at San Remo last May, has deprived us of any further diagrams from his skill, but the example he set will we trust be followed out completely in mathematical diagrammatic instruction.

The unsymmetrical top, discussed in V. § 9, leads into such great analytical complication, that only a few special degenerate cases have so far received any adequate attention; the next century will have its work cut out for the mathematical treatment of this problem and also of the dynamics of the bicycle. The symmetrical top of the boy, with the point free to wander over a smooth or rough horizontal plane, leads to similar analytical difficulties, and should be discussed in the same place.

On the other hand, the many attempts at a popular explanation of the motion of the top, restricted principally to the case of regular precession, are described in V. § 3. Prof. Perry's interesting little book on "Spinning Tops" comes in for praise, and the authors cite with pleasure the comparison of the top to a wilful beast (*eigensinniger Thier*), always ready to move in some other direction to that in which it is pushed; insomuch that the Irishman can persuade his pig to accompany him on the road only by pretending that his way lies in the opposite direction; and so Bessemer's invention to steady the motion of a cabin mounted on gimbals, by means of the controlling influence of gyrostats, was a failure.

If the authors are in search of other practical elementary illustrations, they should take the modern centrifugal machine, and examine the practical devices, as in the Weston machine, for controlling the nutations; these devices discovered experimentally without any assistance from theory will serve to elucidate the abstract formulas with advantage.

A third part of this book is still to appear, and we await it with great interest; the work when complete will form an indispensable book of reference for all who wish to make themselves thoroughly acquainted with this complicated problem in Dynamics.

A. G. GREENHILL.

## *NOTES.*

AT Osborne, on Wednesday, August 2, the Queen conferred the honour of knighthood upon Sir William Henry Preece and Sir Michael Foster, Knight Commanders of the Order of the Bath, and invested them with the riband and badge of the Civil Division of the Second Class of the Order, and affixed the star to their left breasts.

THE Hanbury Gold Medal of the Pharmaceutical Society of Great Britain has been awarded to Prof. Albert Ladenburg, of Breslau, for his work on alkaloids and their derivatives.

MR. J. S. BUDGETT, of Trinity College, Cambridge, who accompanied Mr. Graham Kerr on his expedition in search of *Lepidosiren*, has been successful in obtaining eggs and larvæ of the Crossopterygian Ganoid *Polypterus*. From a short account of his investigations, illustrated by sketches, which Mr. Budgett has sent to this country, it appears that the larva is very minute, and possesses a "cement organ" on the dorsal surface of the head. Mr. Budgett is now on the journey home, and the full account of his work will be looked forward to with much interest.

ON a preceding page we have referred to some of the work performed by the Royal Gardens, Kew. Coincidently we have received the number for July 21 of our American contemporary *Science*, which contains an elaborate article by Prof. Underwood, headed "The Royal Botanic Gardens at Kew," in which the features of the garden and its position as a scientific institution —"its beautiful lawns, its delightful shade, its historic associations, its immense collections of cultivated plants, and its wonderful activity in the direction of botanical research"—are described and discussed with critical appreciation *apropos* the recent establishment of the Botanic Garden of New York and its capability to become "even more influential in democratic America than Kew has become throughout the length and breadth of the Queen's dominions." It is gratifying to have this acknowledgment of the work of Kew; and the tribute paid to the versatility and ability of Sir William Thiselton-Dyer in promoting its development and widening its influence will be everywhere endorsed. There are some blots on the escutcheon in the eyes of Prof. Underwood, but we imagine there are many who will not see with him in all the instances he mentions. The crowding of the museum collections he notes is an apparent blemish, and one we may hope to see removed by the provision of increased room for the exhibition of the specimens. A somewhat jealous comparison of Kew and Berlin as centres of botanical work is a jarring note in the article; and Prof. Underwood allows, we fear, German bias to weigh with him in making it, for instance, when he writes, "the principles of plant distribution are not so thoroughly grasped at Kew as they have been brought out at the German Botanical Garden through the skill of Prof. Engler and his associates." Yet Kew is the home of Sir Joseph Hooker!

FOR several years the need of greater facilities for the publication of mathematical investigations has been strongly felt by the members of the American Mathematical Society. This Society has maintained during the past eight years an historical and critical review, known as the *Bulletin* of the American Mathematical Society, and throughout the whole of this period there has been a constantly growing demand for the publication in the pages of that journal of articles not properly falling within its scope. The co-operation of several American colleges and universities was therefore recently invited in a plan whereby such articles may be afforded suitable means of publication. The necessary co-operation has now been secured, and the publication of a quarterly number of the *Transactions* of the American Mathematical Society has been definitely undertaken to begin January 1, 1900. The *Transactions* will be devoted primarily to research in pure and applied mathematics. The editors will welcome all papers containing investigations of sufficient mathematical interest and value. Such papers, in many cases, will be necessarily of considerable length; but the editors will be very glad to receive, also, short contributions which are of such a character as to fall within the scope of the *Transactions*. Papers from mathematicians not belonging to the Society will be welcomed; such papers, if accepted for publication, will be presented to the Society by the editors. Manuscripts intended for publication in the *Transactions* should be addressed either to Prof. E. H. Moore, University of Chicago, Chicago, Ill., or to Prof. E. W. Brown, Haverford College, Haverford, Pa., or to Prof. T. S. Fiske, Columbia University, New York, N.Y.

BY the will of the late Dr. Jules Maringer, the Pasteur Institute at Paris is bequeathed the sum of one hundred thousand francs.

THE death is announced at Olten, Switzerland, of M. N. Rieggenbach, Correspondant of the Paris Academy of Sciences, in the Section of Mechanics.

*Science* announces the death of Mrs. Elizabeth Thompson, of Stamford, Conn., who made many gifts for benevolent and scientific purposes. She contributed towards the telescope for Vassar College, was one of three "patrons" of the American Association for the Advancement of Science, and endowed the Elizabeth Thompson Science Fund, the income of which is now being so advantageously used for the promotion of scientific research.

A REUTER despatch from St. Petersburg, dated August 2, says:—"News has been received here that the Russian members of the Russo-Swedish Scientific Expedition to Spitsbergen have arrived safely at Horn Sound, where they will winter. Later on they will proceed by land to the western side of the Stor Fiord, where they will engage in geodetic work. Some of the members will not remain over the winter, returning to St. Petersburg in October, but the others will stay in Spitsbergen until the autumn of next year. The Russian members of the expedition have not yet met with their Swedish colleagues; but Prof. Baklund has gone to meet them on board an ice-breaker."

REFERRING to the progress of vaccination, Mr. Chaplin said, in the House of Commons on Thursday last, that the returns which he had obtained showed that the total number of certificates of successful primary vaccination received by the vaccination officers during the first six months of the present year was 353,992 as against 277,821 in the first six months of 1898; that is to say, there has been an increase of upwards of 76,000 primary vaccinations or of more than 27 per cent. in the first six months of the present year as compared with the corresponding period of 1898. These results have been obtained in the first six months of the Act, notwithstanding the difficulty of giving effect to an entire change of method throughout the country from stational to domiciliary vaccination; and also in spite of the fact that in numerous cases there was very considerable delay in the fixing of fees and the appointment of officers.

FROM a note in the *Times* we learn that the section of the famous mpundu tree at Chitambo's, which marked the place where Dr. Livingstone died, has been successfully removed by Mr. Codrington, the Deputy-Administrator of Northern Rhodesia, and will be sent to England for preservation. It will be remembered that two or three years ago Mr. Poulett Weatherley, while exploring in the neighbourhood of Lake Bangweolo, visited Chitambo's and reported that the mpundu tree was in an advanced stage of decay and would probably disappear altogether in a very short time. After careful consideration, the Royal Geographical Society decided that the best course to pursue would be to cut out the section of the tree which bears the inscription and have it sent over to London for preservation at the rooms of the Society. To mark the place where the tree stood, a large cairn has been erected with a staff made of two telegraph poles in the centre, held in place by stays of telegraph wire. This temporary memorial will serve the purpose of preserving the identity of Dr. Livingstone's deathplace until such time as a more permanent memorial is erected.

THE sixth international otological congress was opened on Tuesday at the Examination Hall, Victoria Embankment. Prof. U. Pritchard, the president-elect, was in the chair, and about three hundred aural surgeons from many parts of the world were present. In his presidential address, Prof. Pritchard traced the birth and growth of otological science. Although an ancient Egyptian papyrus had been found on which was written a monograph on deafness and ear diseases, otology, except perhaps with regard to its anatomy and physiology, did not make itself of great importance until the second half of the present century. Between 1840 and 1860 this branch of medical science was vigorously taken up by Sir William Wilde and Toynbee. Since then the means of diagnosis have been considerably improved, while in treatment there has been immense strides, due to the adoption of antiseptic surgery. At the commencement of the present century the ear was regarded almost as a *terra incognita*, scarcely worth consideration except as the seat of one affection only—that which was generally known as "a deafness"—now, at its close, this organ is fully-explored ground, and has been proved well worth the exploration. Otology has been raised from the rank of pseudo-quackery to an honourable position in scientific surgery, and its importance and bearing upon the body as a whole is now fully recognised.

THE results of experiments on the ignition of fire-damp and coal-dust by means of electricity were given in a paper by Herr Heise and Dr. Theim, recently read before the Institution of Mining Engineers. The object of the experiments was to determine to what extent electrically driven machinery is dangerous in fiery or dusty mines. In brief, the sum of the results obtained show that in general the amount of electrical energy which is capable in certain circumstances of igniting fire-damp need only be extremely small. This amount cannot be definitely fixed, however, as it depends not only on the quantity of energy but on the mode of its application and other attendant circumstances. It is only in the case of a current the conditions of which are exactly known that quantitative statements can be made as to the limits of safety for certain classes of transformation of energy. In any case, all visible sparks may be looked upon as dangerous. Experiment alone can decide whether certain classes of sparks

may be devoid of danger. Explosions of coal-dust alone appear to be impossible of production by electricity, unless indeed specially dangerous classes of coal-dust behave differently from those tried.

A COPY of a paper by Dr. J. S. Haldane, F.R.S., and Mr. F. G. Meachem, containing observations on the relation of underground temperature and spontaneous fires in the coal to oxidation and to the causes which favour it, has been received from the Institution of Mining Engineers. The conclusions to which the results of the investigations have led the authors are as follows: (1) A very large amount of heat, sufficient often (if not otherwise absorbed) to heat the air-current to boiling point, is always being formed in a mine, and this heat is almost entirely produced by oxidation of material in the mine. (2) The heat formed greatly exceeds in amount, as a rule, the heat withdrawn by the air-current, so that the temperature of the mine, or of some parts of it, is above that of the strata. (3) The disappearance of oxygen and liberation of heat in the mine are probably due, largely at least, to oxidation of iron pyrites; and the liberation of carbonic acid in the mine is probably due to the action on carbonates of the sulphuric acid thus formed. (4) Coal, when exposed to air, absorbs oxygen, and may also give off carbonic acid and fire-damp, and a very small amount of carbonic oxide. (5) The rate of absorption of oxygen by coal varies directly with the proportion of oxygen present in the air; and as the temperature of the coal increases in arithmetical progression the rate of oxygen-absorption increases in geometrical progression, the ratio of increase (for the coal experimented upon) being about 1/10 for every 4° Fahr. of increase in temperature.

THE engineering papers publish particulars of the series of trials made at Liverpool last week of self-propelled vehicles suitable for heavy traffic. The chief object of the trials was to encourage the development of types of heavy motor wagons suitable for trade and agricultural requirements. The trial runs were made from Liverpool, over distances of from thirty to forty miles, on two successive days. All vehicles were required to traverse the prescribed routes without alternative, and to perform other manœuvres. The distance between any two of the depôts provided for the supply of water did not exceed twelve miles. Steam was used as the motive power in the six vehicles entered for competition this year. Oil was used for fuel in three, coal in two, and coke in one. Electricity and oil motors were unrepresented in the competition. The following awards were made by the judges:—In Class B, for vehicles having a minimum load, 2 tons; maximum tare, 2 tons; minimum level platform area, 50 square feet, a gold medal to the Steam Carriage and Wagon Company (Thorneycroft), Chiswick, and silver medals to Bayley's, Limited, and the Lancashire Steam Motor Company. In Class D, for vehicles with a minimum load of 6½ tons; maximum tare, 4 tons; minimum level platform area, 110 square feet, the gold medal was awarded to the Steam Carriage and Wagon Company (Thorneycroft).

A COMMITTEE of the British Association was appointed in 1896 to take any possible measures to secure uniformity in the pages of scientific transactions and serials, so that parts of various publications can be bound together by those interested in particular subjects. The Committee has already issued one report, and has since been taking steps to bring before the various societies which publish *Proceedings* and *Transactions* the advisability of bringing their publications into harmony, so far as size of paper is concerned, with the standard sizes which already prevail in a great majority of scientific journals and almost uniformly in the case of those longest established. As the result of the inquiries the Committee has issued a circular giving the dimensions of the standard octavo and standard quarto size recommended for scientific publications. It is strongly recommended that every article should always begin at the top of a right-hand page, even if that involves a blank left-hand page, so that a paper can be extracted from a journal without mutilating one or two others.

THE Deutsche Seewarte has published a discussion of the storms experienced in the North Atlantic Ocean during the last week of January and the first weeks of February last. It will be remembered that it was during this exceptionally stormy period that the liners *Pavonia* and *Bulgaria* suffered so severely. The investigation shows that very unusual weather extended from the Rocky Mountains across the whole of the North Atlantic to the Ural Mountains, and that the storms over the British Islands and North-west Europe were accompanied by unusually high temperature, and blizzards occurred over the United States. The principal features of the storms were their great intensity and almost uninterrupted succession, and the period was characterised by the relatively southerly position of the zone in which the principal barometric minima occurred, and pursued the easterly direction in which they usually travel. The work has been prepared by Dr. E. Herrmann, and is illustrated by several charts. We understand that the Meteorological Council are also preparing for publication a more elaborate discussion of this stormy period.

THE Central Physical Observatory and the Geographical Society of St. Petersburg sent up an unmanned balloon on March 24, with duly verified meteorograph. The balloon started about 8 a.m.; in the course of an hour it had attained a height of 10 kilometres and was travelling at the rate of 75 kilometres an hour, according to photogrammetric observations made at Pavlovsk Observatory. The balloon was not found until May 9, 700 kilometres to the east of St. Petersburg. The instruments were in good condition, but the trace had suffered from exposure to the weather. The legible portion showed that at starting the temperature was $-3^{\circ}\cdot8$ F.; at 3900 metres it had fallen to $-29^{\circ}\cdot6$, at 4925 metres to $-41^{\circ}\cdot3$, and at 6559 metres to $-60^{\circ}\cdot1$; at 6878 metres the temperature was $-62^{\circ}\cdot9$, while at the highest point shown by the curve, 7223 metres, the reading had risen to $-61^{\circ}\cdot4$.

A REPORT on clock-rates and barometric pressure as illustrated by the mean-time clock and three chronometers at Mare's Island Observatory, together with a brief account of the observatory, is contributed to the *Publications* of the Astronomical Society of the Pacific, No. 68, by Ensign Everett Hayden, of the U.S. Navy. The paper is illustrated by a diagram of the barometer-rate curve of the mean-time clock, and from this and other tables it is inferred that the best chronometers show a remarkably regular change of rate for differences of pressure, running about ·10s. faster for a decrease of ·10-inch of mean barometer. It is suggested that the rate curves of such chronometers should be drawn for a mean pressure of 30·00 inches, with similar curves to the right and left for each tenth lower and higher pressures, respectively, for, say, five-tenths of an inch, for the practical use of navigators.

A LENGTHY paper on the influence of magnetism on the luminescence of gases has been contributed to the *Bulletin de la Classe des Sciences* of the Belgian Academy (part 6), by M. A. de Hemptinne. The author has studied the action of magnetism on tubes without electrodes excited by electric vibrations; and he examines in succession the influence of the pressure of the gas, the length of the electric wave, the nature of the gas, and the influence of the medium. The paper concludes with theoretical considerations relating to the observed facts.

Part 6 of the *Bulletin de la Classe des Sciences* of the Belgian Royal Academy contains a preliminary report from the Belgian Antarctic Expedition on the soundings of the *Belgica*, drawn up by M. Henryk Arctowsky. Between the channels of Tierra del Fuego and the archipelago of Dirck Gherrits a section was taken of the large Antarctic channel which separates the extremities of the Andes from the hypothetical Antarctic continent. Moreover, within the Antarctic circle and on the west of Alexander Land a series of soundings were taken while the ship was drifting with the pack ice. The principal bathymetric discoveries were (1) a deep flat-bottomed basin between the south side of the Andes and the mountain system forming the framework of the lands visited by the expedition; (2) in places a sharp declivity forming a demarcation to the continental plateau; (3) the existence of a continental plateau west of Alexander Land, and south of the 71st parallel.

From Dr. A. Goldhammer we have received copies of notes published by him in *Wiedemann's Annalen* 65 and 67, dealing, one with modern theories of electromagnetic phenomena in iron, nickel and cobalt, and the other with the Zeeman effect. In the former paper the author compares his equations with those obtained by Mr. J. G. Leathem, of Cambridge.

In the *Journal de Physique* for June, M. Coloman de Szily investigates the effect of torsion on the electric resistance of wires. The substance used in the experiments was an alloy called "constantan," whose resistance is but slightly affected by changes of temperature. The general conclusions are: that torsion increases the electric resistance of a wire; that up to the limit of elasticity the increase is roughly proportional to the angle of torsion, but beyond that limit it increases more rapidly; and that the resistance of a twisted wire decreases slowly with the time.

In *Cosmos*, No. 744, M. A. Acloque discusses the affinities between cadelis-flies and moths. The author considers that even if the distance between the Trichoptera and Lepidoptera is not great, there is at the same time a considerable gap separating them, and that little or no light on the question of a previous connection between the two orders is at present afforded by palæontological considerations.

Dr. Felice dell' Acqua, writing in the *Rendiconti del R. Istituto Lombardo*, brings forward considerations, both statistical and hygienic, relative to the consumption of meat food. It would appear that in Milan the average daily consumption of meat amounts to only $154\frac{1}{2}$ grammes per head of population, and this the author considers is insufficient. After pointing out the desirability of paying greater attention to the diet, especially of working people, Dr. dell' Acqua discusses the beneficial effects of a fair proportion of meat on the general physique. The various ways of increasing the supply of meat are considered. Dr. dell' Acqua strongly urges the desirability of breeding more cattle in Italy, and of not slaughtering immature animals. Of other sources capable of yielding greater supply than at present, the author calls attention to fish, rabbits and birds, and he suggests the acclimatisation of foreign animals and even the use of horse-flesh. It would appear that in Italy considerably less animals are slaughtered for food in proportion to the population than in France or Germany, or especially England.

Under the title "The Honey Bee: a Manual of Instruction in Apiculture," by Mr. Frank Benton, the U.S. Department of Agriculture published a very useful *Bulletin* three or four years ago. Twenty-one thousand copies of the manual have been distributed; and the third edition, containing a few additions and changes, has now been published. The magnitude of the apiarian industry in the United States may be judged from the fact that more than 300,000 persons are engaged in the culture of bees, and the present annual value of apiarian products is estimated at 4,000,000*l*. Mr. Benton states, however, that the present existing flora of the United States could support ten times the number of colonies of bees it now supports. An advantage of this branch of agricultural industry is that it does not impoverish the soil in the least, but, on the contrary, results in better seed and fruit crops. For instance, Dr. L. O. Howard points out that recent investigations have shown that certain varieties of peas are nearly or quite sterile unless bees bring pollen from other distinct varieties for their complete cross fertilisation. Mr. Benton's treatise will continue to be of great assistance to persons engaged in the management of bees for profit.

In the *Verhandlungen der k. k. geol. Reichsanstalt*, Nos. 6 and 7, 1899, Dr. M. Remeš deals with the question of palæontological divisions in the Tithonian limestone of Stramberg. This limestone, as is well known, has yielded a varied and specially interesting assemblage of life-forms, including types of both jurassic and cretaceous character, and is to be looked upon as representing a true passage series. The author gives a brief account of the attempts that have been made to distinguish divisions of horizon or organic facies in the Stramberg Beds, and points out that insufficient care has hitherto been exercised in keeping separate the fossils collected from the various exposures in the one neighbourhood. With the results of his own studies as a groundwork, as well as the long experience of his father in the same field of observation, Dr. Remeš is enabled to show the character of the fauna collected from five different exposures, and to point out petrographical similarities and differences. He concludes that the Stramberg limestone forms a uniform mass which, while not satisfactorily showing stratification, permits a division according to facies in its different parts. It is found that a separation of the jurassic fauna with *Terebratula moravica* from the cretaceous fauna with *T. janitor*, as proposed by Hébert, cannot be justified: a mingling of jurassic and cretaceous forms occurs in like manner at all the points examined. The division adopted by Dr. Remeš, according to organic facies, is threefold. He distinguishes a cephalopod-facies (in the Kotouč-Schlossberg rock-complex), a coral- and sponge-facies (Gemeindesteinbruch complex), and an echinoderm-facies (in the red limestone of Nesselsdorf). The passage of these single rock-masses into one another is stated to be gradual.

Dr. Th. Tchistovitch has made the toxic properties of eel-serum the basis of some important investigations on the mechanism of immunity. These researches emanate from the laboratories of Profs. Metchnikoff and Roux at the Paris Pasteur Institute, and are published in the *Annales*. Amongst other interesting facts brought to light is the discovery that during the process of immunising an animal against the toxic effect of eel-serum, although it may be trained to resist increasing quantities of the toxin, the *antitoxic* properties of this animal's blood-serum do not increase; on the contrary, the antitoxin of a greater or less degree of strength elaborated during the early stages of the immunising process steadily declines in antitoxic value as the animal gains in power of resisting the toxin. The presence, therefore, in the blood of an immunised animal of an antitoxin of a greater or less degree of strength cannot be held to furnish any information or standard as to the degree of immunity acquired by that animal. Immunity, therefore, depends not solely on the production of an antitoxin in the blood, but on some other mechanism which Dr. Tchistovitch considers may in all probability be dependent upon the leucocytes.

AN account of an investigation of a fungus which has done serious damage to the cacao industry in Trinidad is given in the *Kew Bulletin* (Nos. 145-146). Mr. J. H. Hart, Superintendent of the Royal Botanic Gardens, Trinidad, sent to Kew material for examination, and the report upon it states:—"Microscopic examination revealed the presence of two distinct fungous parasites, one being the well-known *Phytophthora omnivora*, De Bary, a species closely allied to *Phytophthora infestans*, De Bary, the cause of the potato disease; the other a *Nectria*, which proves to be new to science, and will be known as *Nectria Bainii*, the name suggested by Mr. Hart in compliment to Mr. Bain, who first called attention to the disease. The *Phytophthora* was present on all the pods sent, and may be considered as the cause of the present epidemic in Trinidad. The same, or a closely allied species, appears to be the cause of the cacao-pod disease in Ceylon. The *Nectria* appeared on two pods, and this again possesses many points in common with the *Nectria*, which has caused such destruction to cacao trees in Ceylon by attacking the bark of the trunk and branches, as described by Mr. J. B. Carruthers. At present no mention is made of other than the pod-disease in Trinidad, but the fact of a parasitic *Nectria* being present necessitates the prompt execution of measures calculated to prevent the parasite from extending its ravages." Mr. G. Massee describes each of the species, and states the measures which should be taken to combat the disease.

REPORTS on experiments on the manuring of oats, hay, and potatoes, and on the feeding of sheep, conducted in 1898 on farms in the centre and south-west of Scotland, are contained in the sixth annual report just issued by the agricultural department of the Glasgow and West of Scotland Technical College. The director of the experiments is Prof. R. Patrick Wright, and under his guidance a large amount of serviceable information, similar in character to that obtained at the Agricultural Experiment Stations in the United States, Canada, and elsewhere, has been made known. By a scheme framed by the Scotch Education Department, the Agricultural Department of the College referred to has been merged into the newly-formed West of Scotland Agricultural College; so the present report is the last of its series, though it is hoped that under the new college a considerable development of the scope and usefulness of the work of agricultural education and research will be rendered possible.

VOL. I. No. 12, of the Records of the Botanical Survey of India is occupied by Mr. V. F. Brotherus' Contributions to the Bryological Flora of Southern India. A number of new species of moss are described.

THE first part of the second volume of the British Museum Catalogue of the African Plants collected by Dr. Friedrich Welwitsch, dealing chiefly with the monocotyledons of the collection, by Dr. A. B. Rendle, has been published.

MESSRS. SWAN SONNENSCHEIN AND CO. have published a second impression of "An Introduction to the Study of Zoology" by Mr. B. Lindsay. The volume is intended for readers beginning the study of zoology, and its chief distinctive characteristic is said to rest "in its attempt to present the system of classification by grades in a form suited to the necessities of elementary and popular teaching."

THE number of the *Biologisches Centralblatt* for July 15 contains a very useful summary, by Prof. Moebius, of recent advances in our knowledge of the mode of impregnation in Gymnosperms and other flowering plants, derived from the remarkable observations of Webber, Ikeno, Hirasi, Nawaschin, Guignard, and Lotsy. The paper is illustrated by several figures.

TO the practical engineer Molesworth's "Pocket-book of Useful Formulæ and Memoranda" is invaluable. The fact that the twenty-fourth edition, revised and enlarged, has just been published, indicates the extent to which the book has met with approbation. An entirely new electrical section has been added, and will increase the usefulness of what has long been a very serviceable manual.

*Contributions from the Botanical Laboratory* of the University of Philadelphia, Vol. ii. No. 1, is full of interesting papers. Dr. Lucy L. W. Wilson has some observations on the life-history of *Conopholis americana*, a remarkable American parasitic plant belonging to the Orobancheæ. Elizabeth A. Simons gives the results of a series of experiments on the rate of circumnutation of the growing stem of some flowering plants, which she finds to be considerably more rapid than the rate stated by Darwin. Mr. R. E. B. McKenney describes observations on the development of some embryo-sacs, chiefly *Scilla* and *Hyacinthus*. The present publication affords one among many illustrations of the extent to which scientific research is being carried out by ladies in the United States. Out of nine papers in this number, five are by women.

THE first number of the *Yorkshire Ramblers' Club Journal* is a very creditable production. Original contributions, reviews, illustrations, and reprints of articles which have appeared elsewhere are included, dealing with various phases of activity of the Club. Noteworthy among the subjects dealt with are the mountains and snow fields of Norway, and the caves and potholes of Yorkshire. A large number of the caves in the carboniferous limestone still remain unexplored; and the Club is busily engaged in this almost inexhaustible field of "underground mountaineering" and research. The manner in which the work of exploration has been carried on and the results achieved have already conferred distinction upon the Club, no less than on the members who are its pioneers. We shall look to future numbers of the *Journal* for particulars of new explorations.

SEVERAL publications containing the results of meteorological observations have lately come to hand. From Prof. J. M. Pernter we have received vols. 32, 33-35 of the Jahrbücher of the K.K. Central-Anstalt für Meteorologie und Erdmagnetismus, Vienna, containing tabulated results of daily meteorological observations made in Austria during 1895, 1896 and 1898.—The Jahrbuch of meteorological observations made during 1897 at the observatory attached to the *Magdeburgische Zeitung*, edited by Herr R. Weidenhagen, has, in addition to the usual tables, a number of curves showing graphically some of the results.—The Ergebnisse of hourly observations made at Bremen in 1898, edited by Prof. Paul Bergholz, have been published.—Sir Cuthbert E. Peek has issued his annual statement of meteorological observations made at his observatory, Lyme Regis, during 1898. A special tower has been erected for the anemometers, and upon it are placed a Dines' pressure-tube recording anemometer and a Robinson anemometer, so that the two instruments can now be compared under very favourable conditions.

SEVERAL new editions of scientific works have lately been received. The publication, by Mr. Murray, of the third edition of Mr. Edward Whymper's guide to "The Valley of Zermatt and the Matterhorn" and the fourth edition of "Chamonix and the Range of Mont Blanc" is well-timed. All visitors to Switzerland should provide themselves with one or both of these interesting and serviceable handbooks.—A second edition of Prof. Henry Louis's "Handbook of Gold Milling" has been published by Messrs. Macmillan and Co. The book originally appeared in 1893, since which date great advances have been

made in the art of gold extraction. So far as possible, account has been taken of all important processes in bringing the book up to date.—Dr. David Walsh's volume on "The Röntgen Rays in Medical Work" (Baillière, Tindall, and Cox) contains much information of interest to all who desire to know how far Röntgen rays have been utilised in medical and surgical cases. To the physician and surgeon this second edition should be of great service in showing what has been done. Referring to the progress made since the publication of the first edition, Dr. Walsh says: "In practical work the times of exposure are shorter, results more certain, and the merits of the statical machine more widely recognised."—A second edition of "A Text-book of Applied Mechanics," by Prof. Andrew Jamieson, has been published by Messrs. Charles Griffin and Co., Ltd. This book has been revised and extended, the chief additions being in the part on hydraulics and hydraulic machines.—The case for cremation as a means of disposing of the dead is forcibly stated by Sir H. Thompson in "Modern Cremation" (Smith, Elder, and Co.), the third edition of which, revised and much enlarged, has just been published. The volume brings up to the present date the history of the practice of cremation, and of the work of the Cremation Society of England.

THE additions to the Zoological Society's Gardens during the past week include a Tantalus Monkey (*Cercopithecus tantalus*) from West Africa, presented by Mr. W. Knight; two Hairy Armadillos (*Dasypus villosus*), a Geoffroy's Cat (*Felis geoffroii*) from La Plata, presented by Mr. W. Brown; a Magpie (*Pica rustica*), British, presented by Mr. S. B. Goldsmith; a Red-eared Bulbul (*Pycnonotus jocosus*), a Yellow-bellied Liothrix (*Liothrix luteus*) from India, presented by Miss Petrocochino; two Goshawks (*Astur palumbarius*), European, presented by M. P. A. Pichot; three Spotted Tinamous (*Northura maculosa*) from Buenos Ayres, four Rufous Tinamous (*Rhynchotus rufescens*) from Brazil, presented by Mr. Ernest Gibson; two Black-eared Marmosets (*Hapale penicillata*) from South-east Brazil, two Maholi Galagos (*Galago maholi*) from South Africa, a Sooty Phalanger (*Trichosaurus fuliginosus*) from Tasmania, a Malabar Squirrel (*Sciurus maximus*, var. *dealbatus*) from India, a Long-necked Chelodine (*Chelodina longicollis*) from South Australia, two Serrated Terrapins (*Chrysemys scripta*) from North America, deposited; a Grison (*Galictis vittata*) from South America, two Superb Tanagers (*Calliste fastuosa*), a Blue and Black Tanager (*Tanagrella cyanomelaena*) from Brazil, a Thick-billed Tanager (*Euphonia laniirostris*) from Central America, purchased; a Common Mynah (*Acridotheres tristis*) from India, received in exchange.

## OUR ASTRONOMICAL COLUMN.

HOLMES' COMET, 1899 *d* (1892 III.).—A new ephemeris for this comet is given by Mr. H. J. Zwiers in *Astr. Nach.* (Bd. 150, No. 3582). It is important that as many observations as possible should be secured, in order to provide the necessary data for a more correct determination of the orbit.

*Ephemeris for 12h. Greenwich Mean Time.*

COMET SWIFT (1899 *a*).—Observers still interested in this comet, and possessed of the necessary optical means, will find an extended ephemeris in the *Astr. Nach.* (Bd. 150, No. 3583) by Herr J. Moller, of Kiel. The positions and relative brightness are given up to September 16, but it is only with the largest instruments that the comet can be at all detected.

THE NEW ALGOL VARIABLE.—In *Harvard College Observatory Circular*, No. 44, Prof. E. C. Pickering gives an ephemeris for observations of this recently discovered variable. The following are the predicted minima during the nights of the present month:—

*Heliocentric Minima of B.D.* 45°·3062.

1899, August 11, at 11h. 43m.
,, ,, 20, at 15h. 12m.

The position of the star is
R.A. ... 20h. 2·4m.
Decl. ... + 45° 53′ } (1855),

and its normal magnitude about 8·6.

DOUBLE STAR CATALOGUE.—Mr. R. G. Aitken has communicated to the *Astr. Nach.* (Bd. 150, Nos. 3584–5) his observations of 319 double stars made during the year 1898. The measures were made with the filar micrometer, in conjunction with either the 12-inch or 36-inch refractor, at the Lick Observatory. The star places are all reduced to epoch 1900, and the data given are time of observation, position angle, distance of components, and their individual magnitudes.

ELEMENTS OF COMETARY ORBITS.—M. G. Fayet has extended Oppolzer's "Traités des Orbites," and brought it up to date by giving the approximate elements for the year 1900 of all the comets hitherto observed. The list is divided into three portions, dealing with comets having elliptic, parabolic, and uncertain orbits respectively; 106 comets are given with elliptic elements, and 104 with parabolic elements, the dates of observation extending from 1702 to the present time. Fifty-one comets of uncertain elements are given, extending from 137 B.C. to 1880. This list of cometary elements will be especially useful in referring to the elements of any new comet, to see if it is really a new member of the solar system or a return of one previously recorded.

## THE FUR-SEAL HERDS OF THE NORTH PACIFIC.

FEW commercial industries command a more varied or more widely spread series of interests than does the sealing trade of the North Pacific. In addition to the great biological interest attaching to the seal-herds, we have, first of all, a considerable number of Aleuts dwelling on the islands to drive, kill, and skin the seals, and who subsist to a certain extent on seal-flesh. Then there is the revenue drawn by the American and Russian Governments for the right of sealing on their respective islands, as well as the Customs dues levied by the former on the dressed seal-skins when re-imported into their territory. Not to mention the transport of the raw hides, the dressing of the latter and their conversion into commercial seal-skin forms a very important industry in London, which employs a large number of hands. There are, moreover, the vessels and their crews, which have of late years been engaged in pelagic sealing; a large proportion of which sailed from Canadian ports. Finally, there is the manufacture of the finished seal-skin into garments, and the retail sale of the latter.

From all points of view a cordial welcome should, therefore, be extended to the issue by the United States Government of the official Report of the Commissioner in charge of the fur-seal investigations of 1896–97. This Report, which bears the title of "The Fur-Seals and Fur-Seal Islands of the North Pacific Ocean," is in two parts, and comprises the final results of the investigations carried on by the Commissioner and his associates, as well as the recommendations jointly formulated by the American and British members of the International Commission.

The fur-seals of the Northern Pacific comprise three distinct herds, which are stated to keep strictly apart from one another, having each their own breeding-places, feeding-grounds, and routes of migration. The most important of the three herds is the one resorting for breeding purposes in summer to the islands of St. Paul and St. George in the Pribyloff group, situated on the eastern side of Bering Sea. In winter this herd

passes through the channels of the Aleutian chain into the Pacific, ranging as far south as Southern California, and returning to their summer haunts along the American coast. Next in importance is the Komandorski herd, the members of which breed upon Bering and Medui islands in that group, migrating in winter down the eastern coast of Japan, and returning by the same route the following summer. Smallest of all is the Robben Island herd, now restricted to Robben, or Tiuleni Island, in the Sea of Okhotsk, just south of Saghalien, but which formerly also colonised four islands of the Kurile chain. The line of migration of this herd lies through the Sea of Japan, so that it never enters the open Pacific. Whereas the Pribyloff herd, which is the one to which the present Report, so far as published,[1] mainly refers, is the property of the Government of the United States, the other two belong to Russia. So far as can be ascertained, the Komandorski and Pribyloff herds were unknown to man (except during migration) till the discovery of the former islands by Bering in 1741, and of the latter by Pribyloff in 1786.

Hitherto the seals of all three herds have been regarded as constituting a single species, *Otaria* (or *Callorhinus*) *ursina*, although differences in colour, shape, and the character of the fur have long been known to exist between them. From the complete isolation of the three herds, and the apparent absence of intermediate forms, Dr. Jordan, the American Commissioner, feels justified in regarding them as indicating as many distinct species, the leading characteristics of which are indicated in the Report. The typical *ursina* is represented by the Komandorski herd, while to the Pribyloff form is assigned the name *alascana* (*alascanus* if *Callorhinus* be recognised as a genus) and to the Robben Island seals that of *curilensis*. To our own thinking it would have been better if these three forms had been regarded as subspecies, and that such a classification at one time occurred to Dr. Jordan, seems to be indicated by the circumstance that the page (45) of the Report on which they are described is headed "The Subspecies of Fur-Seal."

The fact that the fur-seals resort every summer in great numbers to the Pribyloffs for breeding purposes is doubtless well known to the great majority of our readers, but as some new facts in regard to their period of residence on the islands and their habits while there are recorded in the Report, a brief sketch of this period of their existence may not be out of place.

The old breeding "bulls" are the first to put in an appearance, their average date of landing being about the first of May. The younger bulls do not land till the arrival of the "cows," when they "haul out" and pass round the "rookeries" to places in the rear, or fight their way through the territories of the old bulls in possession. The "bachelors," or immature males, begin to arrive about the same time as the old bulls, usually making their appearance according to age; the smaller seals beginning to predominate after July 9. The older bachelors being alone killed in the Pribyloffs, as many as possible are slaughtered before the arrival of their younger brethren, regular driving usually commencing about June 1. It is about June 10 that the adult cows begin to arrive, their appearance and landing, like that of the adult bulls, being gradual. Their arrival is not, as has been stated to be the case, an occasion of fighting among the old bulls for their possession. As a rule, a female about to land reconnoitres the shore by swimming backwards and forwards, and then lands on the rocks, where she is immediately taken in charge by the nearest bull. If a bull discovers her while attempting to land, she endeavours to escape; but if this is impracticable, she submits and takes her station on shore beside him. When a bull once obtains a cow, his station becomes an objective point for all the others landing in the vicinity, and a "harem" is thus formed; large "harems" being thus constituted in the neighbourhood of favourite landing-places. Soon after landing the cows give birth to their "pups" (one in number to each cow).

In the larger rookeries as many as a hundred cows may go to the formation of a single harem; and so long as they remain quietly resting before and after the birth of their pups, the one bull has no difficulty in keeping them under control. But as soon as the pairing-season sets in (which it does very soon after the birth of the pups) the old bull is unable to manage his harem, and the "idle bulls" around enter the circle. With the "podding" (collection in masses) and scattering of the pups and the influx of fresh cows, the area occupied by the seals gradually extends, and fresh bulls are taken into the circle, until the utmost limits of expansion are reached.

The population of breeding cows gradually increases from the beginning of the season till about the middle of July, from which period it diminishes till the close of the breeding-season, about August 1, the height of the season being about July 15, when the maximum number of breeding cows are on shore. It is not, however, to be assumed that by any means all the cows are then on land—quite the contrary. From about June 10 or 12 onwards fresh cows are constantly arriving at the rookeries, each cow making a sojourn of about ten or twelve days, after which she starts on her first excursion to the feeding-grounds, distant between one and two hundred miles. The height of the season accordingly means merely that the stream of arriving cows is about counterbalanced by the departing one.

Throughout the breeding-season a band of sleeping, playing, and swimming seals skirts the sea-front of each rookery, the majority of these being cows, although some are bachelors. This band includes the arriving and departing cows; the former gradually edging themselves nearer and nearer to the shore, while the latter tend to the seaward fringe. So stealthily is the landing and the departure accomplished, that it is a very difficult matter to observe a cow either in the act of landing or of setting out to sea. One reason of the loitering before landing seems to be to allow time for the complete digestion of the food, which always takes place while at sea. As the bachelors likewise make periodical journeys to the feeding-grounds, it is evident that it is only the bulls which fast throughout the breeding-season; and for the purpose of enduring this, they accumulate a thick layer of blubber previous to landing.

On landing from one of her feeding expeditions the cow calls lustily for her pup, on finding which she forthwith proceeds to nurse it, the pup then departing and taking no further notice of its parent till it again requires a meal. As the majority of the cows are at sea, a landing cow is immediately surrounded by hungry, and it may be starving, pups, who are driven away with decidedly savage treatment. The pups are entirely dependent upon their own mother's milk till about November, the Commission scouting the idea that there is any promiscuous feeding of the pups by the cows, or that the former subsist in part on a vegetable diet.

Mention remains to be made of the landing of the yearling and two-year-old females, whose brothers come to the islands about the first of July and spend their time on the hauling grounds. The two-year-old females reach the rookeries about August 1, and take up their places either in the old harems, or in fresh ones in front of and behind the regular breeding-grounds. Here they are taken charge of by young bulls, and after a short sojourn return to the water. Although the yearling cows apparently arrive with the two-year-olds, they do not make their appearance on the rookeries much before September, and then spend their time in ranging over the latter and playing with the pups, which by this time have become strong swimmers.

In regard to the breaking up of the breeding-season, the old harem-bulls, who have fasted from the beginning of May, begin to desert the rookeries for the feeding-grounds about July 25, their places being taken by the idle bulls. By some time between August 5 and 10, all the adult bulls have departed; the breeding-grounds being then occupied by the younger bulls and bachelors, who, however, soon return to the sand beaches. At the first approach of winter, which usually occurs in November, the cows and pups start on their journey southward. The bachelors linger for some time longer, in some years a considerable number remaining till the end of December or even well on in January; while in mild seasons some may be seen all through the winter. As a rule, however, November ends the sojourn of the seals on the Pribyloffs, and, class by class, they set out on their winter migration.

Such is, very briefly, the life-history of the fur-seals during their sojourn around and on the Pribyloffs. We now proceed to notice, with equal brevity, the decline which has of recent years taken place in the numbers of the herd, the reasons for such decline, and the remedies suggested for its recovery. Since these islands came under the sway of the United States Government only bachelors of a certain age have been allowed to be killed on shore. From 1869 to 1889 the sealing rights were leased to the Alaska Commercial Company, whose annual quota of skins was limited to 100,000, of which 75,000 were to be taken on St. Paul and the remainder on St. George. On

[1] Two other parts of the Report are announced, the second (iv.) of which will deal with the Komandorski and Robben Island herds.

the expiration of this lease the islands were relet for a period of twelve years to the North American Commercial Company, on more advantageous terms, the quota of skins being fixed for the first year at 60,000, while it has since been under the regulation of the Secretary to the Treasury.

Putting aside for subsequent mention the question of pelagic sealing, it may be observed that between the years 1871 and 1875 the number of breeding seals and young on the islands was estimated by Mr Elliott, in round numbers, at 3,193,000. In spite, however, of the fact that this observer did not recognise that only a portion of the cows were on land at any one time, the Commission concludes that this estimate is far too high, and that 1,400,000 would have been a much closer approximation to the truth. They further state that between 600,000 and 700,000 seems to be a fair estimate of the number of breeding females resorting annually to the islands between the years 1871 and 1885; while at the present time (1896–97) the number is only about one fifth of what it then was.

As regards the decline of the Pribyloff herd, the best evidence is afforded by the fact that whereas between the years 1871 and 1885 no difficulty was experienced in obtaining the full number of 100,000 bachelor seals of the proper age before July 20, in 1896 it was only found possible to obtain 30,000 fit for killing even by continuing the drives till July 27; while in the following year, when driving was carried on as late as August 11, only 20,890 were obtained. It is largely on these data that the above-mentioned estimate of the former number of breeding animals is founded.

The life of the female seal being estimated at from ten to fifteen years, thirteen years may be taken as an average, during ten of which she is capable of producing young. On this estimate 10 per cent. of the breeding females die of old age each winter, in addition to those which perish from other causes. The stock is replenished by the annual addition of the three-year-old females. Among the young and pups the death-rate from natural causes is very high; about two-thirds thus perishing annually before they attain the age of three years, when the females are fit for breeding and the males for killing. The most important of such natural causes are the presence of a parasitic worm on the sandy breeding-grounds, the trampling to death by the ordinary movements or fights of the adults, starvation of the pups from being separated from their mothers at a very early age, destruction by the killer-whale, and drowning during the winter storms.

In 1896 the number of females with pups on the islands was about 157,000, and in the following year 130,000. In certain rookeries the number of pups had diminished from about 16,240 in 1896 to about 14,320 in 1897, indicating a decrease of about 12 per cent., the number of harems having likewise diminished by about $10\frac{1}{2}$ per cent. Although precise figures are not available, the total decrease in the number of breeding females for the same period may be put down at about 15 per cent., and that of the males fit for killing at about 30 per cent.

Although the exact number to which it is safe to reduce the breeding bulls in a rookery as compared to the cows has not yet been ascertained, it is quite certain that in the Pribyloff herd there is no reduction of the former to anything near that limit. Consequently the killing carried on in the islands cannot be held responsible for the serious reduction which has of late years taken place in the numbers of the herd. On the contrary, such thinning out of the bachelors has tended to the actual increase of the breeding herd, owing to the less amount of fighting which takes place when the bulls are reduced in number, and the consequent diminished loss of life among the cows and pups owing to such fights.

On the other hand, there is every reason for believing that the waning of the herd is solely to be attributed to pelagic sealing, in which the number of females taken is very largely in excess of the males, while for each female so killed an unborn pup is also destroyed, and in the case of those which have already bred a second pup is starved miserably to death on land. Since the normal rate of increase of the breeding herd is a little short of 17 per cent., while the natural death-rate from old age is not far from 10 per cent., it follows (without allowing for other natural causes of death among the adults) that not more than about 6-2/3 per cent. of the females can be destroyed by human agency year by year without involving the ultimate destruction of the herd. This limit has been very largely exceeded as the result of pelagic sealing, in which (in spite of statements to the contrary) it is impossible to distinguish females from males until too late; and in consequence of this the Pribyloff herd has been so reduced that neither pelagic nor land sealing yields an adequate profit on the money invested. The Commission, indeed, go so far as to say that from a commercial point of view the herd is virtually destroyed. "But this," they add, "has not involved the biological destruction of the herd. Under wise protection it may regain its former numbers." That such protection (which involves the prohibition of the killing of females, and therefore apparently also of pelagic sealing[1]) may be extended to the herd while there is yet time, must be the hope of every naturalist. R. L.

## *INHERITANCE OF LONGEVITY IN MAN.*

THE object of this paper[2] is twofold, namely:—

(1) To ascertain whether duration of life is inherited, and

(2) To exhibit natural selection at work in man.

According to both Wallace and Weismann the duration of life in any organism is determined by natural selection. An organism lives so long as it is advantageous, not to itself, but to its species that it should live. But it would be impossible for natural selection to determine the fit duration of life, as it would be impossible for it to fix any other character, unless that character were inherited. Accordingly a preliminary inquiry as to whether duration of life is inherited or not seems needful before we consider further the plausibility of Wallace and Weismann's hypothesis. The present paper shows that directly and collaterally duration of life is certainly inherited in the male line. We believe this to be the first quantitative measure of the inheritance of life's duration. Further data for the inheritance of this character in the female line, and for the study of the inheritance of "brachybioty" or shortlivedness as distinguished from longevity are now being collected. We point out in the paper and endeavour to illustrate by examples the importance of such quantitative measure of the inheritance of life's duration for actuarial practice.

The second aim of our paper seems to us, perhaps, to have the greater scientific importance. In the presidential address at the Oxford meeting of the British Association we were told that no one had seen natural selection at work. In a criticism then published by one of us, it was suggested that every one who had examined a mortality table had seen natural selection at work. Now the meaning of natural selection is absolutely simple. All individuals die, but some, better suited by their constitution and characters to their environment than others, survive longer, and so are able, or better able, to reproduce themselves, and to protect for a longer period their offspring. To assert that natural selection does not exist, is to assert that the whole death-rate is non-selective, or is not a function of the constitution and characters of the individual. Looked at from this standpoint the existence of natural selection really becomes a truism. All that remains when we desire to see it at work is to determine the relative amounts of the selective and non-selective parts of the death-rate for individuals living under the like environment. If, therefore, individuals living under much the same conditions are dealt with, the determination of the selective and non-selective death-rates is a measure of the quantitative amount of natural selection. Now we can answer this problem in two ways. First we may take any organ, and determine whether the death-rate is a function of the size of this organ. This method, adopted by Prof. Weldon, would be the direct and best method, if the results were not apt to be screened by other factors. In the first place we have to hit upon some organ upon which vitality largely and sensibly depends; and this is not easy, for constitutional power of resisting the attacks of disease may depend upon, not one organ, but on the complex relationships of a system of organs, and in the next place the whole problem is rendered difficult by changes due to growth. In the second method we do not attempt to select any organ whatever, but select individuals having any general

[1] The writer takes this opportunity of mentioning that, misled by a summary of some of the evidence given before the Paris Commission, he was inclined in the "Royal Natural History" to pronounce pelagic sealing more humane than seal-killing on land.

[2] "Data for the Problem of Evolution in Man. II. A First Study of the Inheritance of Longevity and the Selective Death-rate in Man." By Miss Mary Beeton and Karl Pearson, F.R.S., University College, London. Received May 29. (Abstract of a paper read before the Royal Society, June 15.)

resemblance in their constitution, or in the whole complex of organs and characters, and correlate their fitness for surviving. Now relations or members of the same family are precisely such individuals. If there were no selective death-rate there would be no correlation between the ages of death of, say, brothers. If there were no non-selective death-rate, we ought to find that the correlation between ages of death of brothers takes the value determined for the coefficient of heredity in brothers, *e.g.* the ·4 of stature, fore-arm, cephalic index, eye colour, &c., Actually we find it to be something sensibly less than ·4. Our investigation shows that, in round numbers, about 80 per cent. of the death-rate is selective in the case of mankind. To that extent natural selection is actually at work. Combined with the quantitative measures of heredity already published, or obtained if not yet published, we can safely conclude that Darwin's theory of a progressive change due to natural selection combined with heredity applies even to mankind to an extent which can be quantitatively measured. The next stage must be an experimental one. Various types of life ought to be submitted to ordeals of a kind like to those which occur in nature, and the correlation between the powers of resistance to these ordeals existing in members of the same family or brood determined. We shall thus be able to ascertain under a variety of circumstances the relative proportions of the selective and non-selective death-rates. A careful inspection of the characters of the longer-lived families may possibly enable the trained biologist to select some organs or characters to which a direct application of Prof. Weldon's method can be made, and thus enable us to distribute, so to speak, the total selective death-rate previously discovered among its chief factors; but here it must be remembered that relationship of organs may be quite as important as absolute size. The present paper is merely a preliminary study of the selective death-rate in man; but one may venture to express a hope that in a comparatively few years, if enough workers can be found for the experimental side of the subject, we shall no longer hear natural selection spoken of as hypothetical, but rather its quantitative measure given for various organisms under divers environments.

## THE CAUSE AND PREVENTION OF MALARIA.[1]

I HAVE the honour to address you, on completion of my term of special duty for the investigation of malaria, on the subject of the practical results as regards the prevention of the disease which may be expected to arise from my researches; and I trust that this letter may be submitted to Government if the Director General thinks fit.

It has been shown in my reports to you that the parasites of malaria pass a stage of their existence in certain species of mosquitoes, by the bites of which they are inoculated into the blood of healthy men and birds. These observations have solved the problem—previously thought insolvable—of the mode of life of these parasites in external nature.

My results have been accepted by Dr. Laveran, the discoverer of the parasites of malaria; by Dr. Manson, who elaborated the mosquito theory of malaria; by Dr. Nuttall, of the Hygienic Institute of Berlin, who has made a special study of the relations between insects and disease; and, I understand, by M. Metchnikoff, Director of the Laboratory of the Pasteur Institute in Paris. Lately, moreover, Dr. C. W. Daniels, of the Malaria Commission, who has been sent to study with me in Calcutta, has confirmed my observations in a special report to the Royal Society; while, lastly, Prof. Grassi and Drs. Bignami and Bastianelli, of Rome, have been able, after receiving specimens and copies of my reports from me, to repeat my experiments in detail, and to follow two of the parasites of human malaria through all their stages in a species of mosquito called the *Anopheles claviger*.

It may, therefore, be finally accepted as a fact that malaria is communicated by the bites of some species of mosquito; and, to judge from the general laws governing the development of parasitic animals, such as the parasites of malaria, this is very probably the only way in which infection is acquired, in which opinion several distinguished men of science concur with me.

In considering this statement it is necessary to remember that it does not refer to the mere recurrences of fever to which people previously infected are often subject as the result of chill, fatigue, and so on. When I say that malaria is communicated by the bites of mosquitoes, I allude only to the original infection.

It is also necessary to guard against assertions to the effect that malaria is prevalent where mosquitoes and gnats do not exist. In my experience, when the facts come to be inquired into, such assertions are found to be untrue. Scientific research has now yielded so absolute a proof of the mosquito theory of malaria that hearsay evidence opposed to it can no longer carry any weight.

Hence it follows that, in order to eliminate malaria wholly or partly from a given locality, it is necessary only to exterminate the various species of insect which carry the infection. This will certainly remove the malaria to a large extent, and will almost certainly remove it altogether. It remains only to consider whether such a measure is practicable.

Theoretically the extermination of mosquitoes is a very simple matter. These insects are always hatched from aquatic larvæ or grubs which can live only in small stagnant collections of water, such as pots and tubs of water, garden cisterns, wells, ditches and drains, small ponds, half-dried watercourses, and temporary pools of rain-water. So far as I have yet observed the larvæ are seldom to be found in larger bodies of water, such as tanks, rice-fields, streams and rivers and lakes, because in such places they are devoured by minnows and other small fish. Nor have I ever seen any evidence in favour of the popular view that they breed in damp grass, dead leaves, and so on.

Hence, in order to get rid of these insects from a locality, it will suffice to empty out or drain away, or treat with certain chemicals, the small collections of water in which their larvæ must pass their existence.

But the practicability of this will depend on circumstances—especially, I think, on the species of mosquito with which we wish to deal. In my experience, different species select different habitations for their larvæ. Thus the common "brindled mosquitoes" breed almost entirely in pots and tubs of water; the common "grey mosquitoes" only in cisterns, ditches and drains; while the rarer "spotted-winged mosquitoes" seem to choose only shallow rain-water puddles and ponds too large to dry up under a week or more, and too small or too foul and stagnant for minnows.

Hence the larvæ of the first two varieties are found in large numbers round almost all human dwellings in India; and, because their breeding grounds—namely, vessels of water, drains and wells—are so numerous and are so frequently contained in private tenements, it will be almost impossible to exterminate them on a large scale.

On the other hand, spotted-winged mosquitoes are generally much more rare than the other two varieties. They do not appear to breed in wells, cisterns and vessels of water, and therefore have no special connection with human habitations. In fact it is usually a matter of some difficulty to obtain their larvæ. Small pools of any permanence—such as they require—are not common in most parts of India, except during the rains, and then pools of this kind are generally full of minnows which make short work of any mosquito larvæ they may find. In other words, the breeding grounds of the spotted-winged varieties seem to be so isolated and small that I think it may be possible to exterminate this species under certain circumstances.

The importance of these observations will be apparent when I add that hitherto the parasites of human malaria have been found only in spotted-winged mosquitoes—namely, in two species of them in India and in one species in Italy. As a result of very numerous experiments I think that the common brindled and grey mosquitoes are quite innocuous as regards human malaria—a fortunate circumstance for the human race in the tropics. And Prof. Grassi seems to have come to the same conclusion as the result of his inquiries in Italy.

But I wish to be understood as writing with all due caution on these points. Up to the present our knowledge, both as regards the habits of the various species of mosquito and as regards the capacity of each for carrying malaria, is not complete. All I can now say is that if my anticipations be realised—if it be found that the malaria-bearing species of mosquito multiply only in small isolated collections of water which can easily be dissipated—we shall possess a simple mode of eliminating malaria from certain localities.

I limit this statement to certain localities only, because it is obvious that where the breeding pools are very numerous,

[1] Report from Major Ronald Ross to the Secretary to the Director General, Indian Medical Service, Simla. Dated Calcutta, February 16.

as in water-logged country, or where the inhabitants are not sufficiently advanced to take the necessary precautions, we can scarcely expect the recent observations to be of much use—at least for some years to come. And this limitation must, I fear, exclude most of the rural areas in India.

Where, however, the breeding pools are not very numerous, and where there is anything approaching a competent sanitary establishment, we may, I think, hope to reap the benefit of these discoveries. And this should apply to the most crowded areas, such as those of cities, towns and cantonments, and also to tea, coffee, and indigo estates, and perhaps to military camps.

For instance, malaria causes an enormous amount of sickness among the poor in most Indian cities. Here the common species of mosquitoes breed in the precincts of almost all the houses, and can therefore scarcely be exterminated; but pools suitable for the spotted-winged varieties are comparatively scarce, being found only on vacant areas, ill-kept gardens, or beside roads in very exceptional positions where they can neither dry up quickly nor contain fish. Thus a single small puddle may supply the dangerous mosquitoes to several square miles containing a crowded population: if this be detected and drained off—which will generally cost only a very few rupees—we may expect malaria to vanish from that particular area.

The same considerations will apply to military cantonments and estates under cultivation. In many such malaria causes the bulk of the sickness, and may often, I think, originate from two or three small puddles of a few square yards in size. Thus in a malarious part of the cantonment of Secunderabad, I found the larvæ of spotted-winged mosquitoes only after a long search in a single little pool which could be filled up with a few cart-loads of town rubbish.

In making these suggestions I do not wish to excite hopes which may ultimately prove to have been unfounded. We do not yet know all the dangerous species of mosquito, nor do we even possess an exhaustive knowledge of the haunts and habits of any one variety. I wish merely to indicate what, so far as I can see at present, may become a very simple means of eradicating malaria.

One thing may be said for certain. Where previously we have been unable to point out the exact origin of the malaria in a locality, and have thought that it rises from the soil generally, we may now hope for much more precise knowledge regarding its source; and it will be contrary to experience if human ingenuity does not finally succeed in turning such information to practical account.

More than this, if the distinguishing characteristics of the malaria-bearing mosquitoes are sufficiently marked (if, for instance, they all have spotted wings), people forced to live or travel in malarious districts will ultimately come to recognise them and to take precautions against being bitten by them.

Before practical results can be reasonably looked for, however, we must find precisely—

(*a*) What species of Indian mosquitoes do and do not carry human malaria.

(*b*) What are the habits of the dangerous varieties.

I hope, therefore, that I may be permitted to urge the desirability of carrying out this research. It will no longer present any scientific difficulties, as only the methods already successfully adopted will be required. The results obtained will be quite unequivocal and definite.

But the inquiry should be exhaustive. It will not suffice to distinguish merely one or two malaria-bearing species of mosquito in one or two localities; we should learn to know all of them in all parts of the country.

The investigation will be abbreviated if the dangerous species be found to belong only to one class of mosquito, as I think is likely; and the researches which are now being energetically entered upon in Germany, Italy, America and Africa will assist any which may be undertaken in India, though there is reason for thinking that the malaria-bearing species differ in various countries.

As each species is detected it will be possible to attempt measures at once for its extermination in given localities as an experiment.

I regret that, owing to my work connected with *kala-azar*, I have not been able to advance this branch of knowledge as much during my term of special duty as I had hoped to do; but I think that the solution of the malaria problem which has been obtained during this period will ultimately yield results of practical importance.

## *UNIVERSITY AND EDUCATIONAL INTELLIGENCE.*

THE *Times* reports that the University of Berlin celebrated on Thursday last the ninetieth anniversary of its foundation by Frederick William III. The oration was delivered by the retiring rector, Dr. Waldeyer, professor of anatomy, who took for his text the question, "Does the University of Berlin fulfil the mission entrusted to it by its founder?" As a contribution to the discussion of this question, he gave a learned and interesting account of the history of anatomical teaching in Berlin. Dr. Waldeyer is succeeded as rector by Prof. Fuchs, the distinguished mathematician.

THE Research Fellowships founded by the Salters' Company and the Leathersellers' Company for the encouragement of higher research in chemistry in its relation to manufactures, tenable at the City and Guilds Central Technical College, being now vacant, the Executive Committee of the City and Guilds of London Institute will, before the commencement of next session, consider applications and elect candidates. The grant made by each of the companies to the Institute for this purpose is 150*l.* a year. Copies of the schemes under which the Fellowships will be awarded may be had on application to the Honorary Secretary of the Institute, Gresham College, Basinghall Street, E.C.

A COPY of the twenty-third annual "Catalogue" of the Agricultural and Mechanical College of Texas has been received. All the departments of the College appear to be well equipped, and the buildings and grounds are of a very extensive character. The course of work at the College is designed to enable young men "to obtain that education and training which will fit them to take a leading part in the material development of the State; to become scientific farmers and horticulturists, familiar with the properties and needs of soils, the laws of plant growth, the principles of breeding, and, in general, with rational methods based on the revelations of modern science; to become mechanical engineers, draughtsmen, chemists, civil engineeers, competent to fill responsible positions in these callings—men fitted not only to meet demands made upon them, but to create such demand by pointing the way to progress and development."

THE Royal Naval Engineering College at Keyham was visited by members of the Institution of Mechanical Engineers during the recent meeting at Plymouth, and the excellent opportunities afforded for the efficient training of the engineer students, who are being instructed both theoretically and practically to enable them to become engineer officers in the Royal Navy, were seen. For the last eleven years Keyham has been the only Admiralty training ground for these officers. An entry is made once each year, during the first or second week in July, following a competitive examination held by the Civil Service Commissioners in the previous April. The period of training is five years. Throughout this time they undergo an educational course at the Royal Naval Engineering College under Prof. A. M. Worthington, F.R.S., whilst their practical training is obtained in the dockyard at Keyham, and the work they perform is as far as possible real. In a paper read before the Institution of Mechanical Engineers, Mr. R. Mayston pointed out that the facilities afforded at Keyham for the acquirement of a thoroughly practical training place the Royal Naval Engineering College in the foremost rank as an institution for obtaining a sound knowledge of mechanical engineering. The fact that as soon as possible after entry the student is employed on useful work, the various courses of instruction which are arranged to render the knowledge of marine engineering obtained as complete and as comprehensive as possible, the facilities afforded for acquaintance with running machinery, the constant contact throughout the training with experienced workmen, the frequent opportunities afforded for obtaining information from the officers who have charge of the training, all go to indicate that nothing is spared to make the training of the engineer student as complete as possible. It may, indeed, be accurately said that Keyham College furnishes an example of what technical education should mean, namely, a wise combination of theoretical and practical work.

HER Majesty's Commissioners for the Exhibition of 1851 have made the following appointments to Science Research Scholarships for the year 1899, on the recommendation of the authorities of the respective Universities and Colleges. The scholarships are of the value of 150*l.* a year, and are ordinarily tenable for two years (subject to a satisfactory

report at the end of the first year) in any University at home or abroad, or in some other institution approved of by the Commissioners. The scholars are to devote themselves exclusively to study and research in some branch of science, the extension of which is important to the industries of the country. A limited number of the scholarships are renewed for a third year where it appears that the renewal is likely to result in work of scientific importance.

| | Nominating institution | Scholar |
|---|---|---|
| 1 | University of Glasgow | Robert John Tainsh Bell |
| 2 | University of St. Andrews | James C. Irvine |
| 3 | Mason University College, Birmingham | Henry Leonard Heathcote |
| 4 | University College, Bristol | Winifred Esther Walker |
| 5 | Yorkshire College, Leeds | Frederick William Skirrow |
| 6 | University College, Liverpool | Charles Glover Barkla |
| 7 | University College, London | Harriette Chick |
| 8 | University College, London | Henry James Tomlinson |
| 9 | Owens College, Manchester | Frank Austin Lidbury |
| 10 | Durham College of Science, Newcastle-upon-Tyne | William Campbell |
| 11 | University College, Nottingham | Louis Lownds |
| 12 | University College of Wales, Aberystwyth | James Travis Jenkins |
| 13 | University College of North Wales, Bangor | Robert Duncombe Abell |
| 14 | Queen's College, Belfast | William Caldwell |
| 15 | McGill University | William Brown McLean |
| 16 | University of Melbourne | Bertram D. Steele |

The following scholarships granted in 1898 have been continued for a second year on receipt of a satisfactory report of work done during the first year:—

| | Nominating iostitution | Scholar | Place of study |
|---|---|---|---|
| 1 | University of Glasgow | James Frank Bottomley | Owens College; to proceed to University College, London |
| 2 | University of Aberdeen | Alexander Findlay | University of Leipzig |
| 3 | Mason College, Birmingham | A. H. Reginald Buller | Botanical Institute, Leipzig; to proceed to University of Munich |
| 4 | Yorkshire College, Leeds | Harry Thornton Calvert | University of Leipzig |
| 5 | University College, Liverpool | Ernest Brown | Central Technical College, South Kensington |
| 6 | Owens College, Manchester | James Henry Smith | Owens College (*permitted under special circumstances*) |
| 7 | Durham College of Science, Newcastle-upon-Tyne | Arthur William Ashton | University College, London |
| 8 | University College, Nottingham | Austin Henry Peake | Cavendish Laboratory, Cambridge |
| 9 | Royal College of Science for Ireland | Robert L. Wills | Cavendish Laboratory, Cambridge |
| 10 | Queen's College, Galway | Hugh Ryan | University of Berlin |
| 11 | University of Toronto | William Gabb Smeaton | University of Leipzig |
| 12 | Dalhousie University, Halifax, Nova Scotia | Ebenezer Henry Archibald | Harvard University |

The following scholarships granted in 1897 have been exceptionally renewed for a third year:—

| | Nominating institution | Scholar | Place of study |
|---|---|---|---|
| 1 | University of Glasgow | James Muir | Engineering Laboratory, Cambridge |
| 2 | University of St. Andrews. | Harry McDonald Kyle | Gatty Marine Laboratory, St. Andrews, Laboratoire Arago, Banyuls-sur-mer; Konigliche Biologische Anstalt, Heligoland |
| 3 | University College, Bristol | Charles Henry Graham Sprankling | Owens College, Manchester |
| 4 | Yorkshire College, Leeds | Harold Albert Wilson | Cavendish Laboratory, Cambridge |
| 5 | University College of South Wales and Monmouthshire | Maria Dawson | Botanical Laboratory, Cambridge |
| 6 | University of Melbourn | Walter Rosenbain | Engineering Laboratory, Cambridge |

IN connection with the article on the duties of provincial professors, which recently appeared in these columns, it is worthy of note that, according to the *Hochschul-Nachrichten*, 22 per cent. of the professors in the German universities are engaged in lecturing or laboratory supervision two to six hours a week, and 51 per cent. from seven to twelve hours. Of the associate professors 60 per cent. are engaged from two to six hours per week, and of the privatdocents 82 per cent. Only 4 per cent. of all privatdocents are engaged in lecturing or laboratory supervision more than twelve hours a week. As *Science* remarks, the leisure of the German associate professors and docents explains in large measure the amount of research work accomplished in German universities.

## SCIENTIFIC SERIAL.

*American Journal of Mathematics*, vol. xxi, No. 3, July.—This number opens with a long memoir (64 pp.) by Dr. L. E. Dickson, entitled "Determination of the Structure of all Linear Homogeneous Groups in a Galois Field which are defined by a Quadratic Invariant." This is an attempt at a complete determination of this important type of groups. Dr. Dickson's work is familiar to the students of "groups" in this country by his papers in the *Quarterly Journal* (on the first hypoabelian group generalised, 1898), in the American *Bulletin* (the structure of the hypoabelian groups, July 1898, also of the *Bulletin* for February and May 1898), and in the *Proc. of the Lond. Math. Soc.* (the structure of certain linear groups with quadratic invariants, vol. xxx. pp. 70-98). Two new systems of simple groups are obtained in the present memoir, and thereby some results in the earlier papers are correlated and completed. (References are freely given to results obtained by other workers in this field.)—Upon the ruled surfaces generated by the plane movements whose centrodes are congruent conics tangent at homologous points, by Dr. E. M. Blake. The movements considered are thus defined. Upon a plane $\alpha'$ containing a conic C′ moves a coincident plane $\alpha$, containing a conic C congruent to C′, in such a manner that C and C′ are always tangent at homologous points, *i.e.* C and C′ are the centrodes of the movement. The locus of a point rigidly attached to $\alpha$ is a curve of the fourth order when C and C′ are central conics, and of the third order when they are parabolas. The locus is in a plane parallel to $\alpha'$, and the same distance from it that the generating point is from $\alpha$. The locus of a straight line carried by $\alpha$ and making an angle with it, is a quartic scroll when the centrodes are central conics, and a cubic scroll when they are parabolas. The object of the paper is to describe the forms of these scrolls, and the character and situation of their nodal lines and pinch-points. The results are to be regarded (1) as furnishing a method of mechanically generating certain cubic and quartic scrolls, and (2) as exhibiting the totality of line-loci of the movements considered. These results are believed, by the author, to be new.—The remaining two papers are by J. C. Glashan, and their nature is indicated by their titles, viz. "Quinquisection of the Cyclotomic Equation" (read, in abstract, at the British Association meeting of August 29, 1897, *cf.* Prof. Cayley's paper on the subject in vol. xii. of the *L. Math. Soc. Proc.*), and on the *m* fold section of the cyclotomic equation in the case of *m* prime. (Useful references are given to previous memoirs on the subject.)—Accompanying this number is an index to volumes xi.-xx.—The editorial staff is announced to consist of Prof. Newcomb, with the co-operation of A. Cohen, Frank Morley, Charlotte A. Scott, and other mathematicians.—This is strong enough for any work that may be placed before it.

## SOCIETIES AND ACADEMIES.

### LONDON.

**Royal Society**, June 15.—"On the Waters of the Salt Lake of Urmi." By R. T. Günther, M.A., and J. J. Manley, Daubeny Curator, Magdalen College. Communicated by Sir John Murray, F.R.S.

This paper contains an account of a physical and chemical investigation of the waters of the great salt lake of Urmi in Azerbaijan, North-west Persia. Samples of the water were

collected by Mr. R. T. Günther during his expedition to the lake last summer, and were examined by Mr. J. J. Manley in the laboratory of Magdalen College, Oxford. The specific gravity of one of the samples of the water at 15° C. was about 1·11338; its boiling point under normal conditions in a platinum bottle was 103·84° C., as determined by a form of platinum resistance thermometer. The refractive index ($\mu$) was found to be 1·36110 by a method which the authors consider to be applicable to ordinary sea waters, and to be capable of yielding an indication of the physical nature of the water which is both more accurate and more readily obtainable than the ordinary specific gravity. The chemical examination was, with a slight modification, similar to that employed by Dittmar in his work on the composition of the ocean water collected by the *Challenger*. The hypothetical proximate composition of 100 parts of the total salts was calculated with the following results:—

| | |
|---|---|
| Sodium chloride ... ... | 86·332 |
| Magnesium chloride ... ... | 6·661 |
| Magnesium sulphate ... ... | 4·211 |
| Calcium sulphate ... ... | 0·988 |
| Potassium sulphate ... ... | 1·741 |
| | 99·933 |

A trace of barium was detected by the spectroscope. No iodine or bromine could be discovered.

It is to be hoped that the constitution of the lake water will be determined again at intervals of a few years, in order to show whether or not the salinity is undergoing any change, and if so, in which direction.

PARIS.

**Academy of Sciences**, July 31.—M. van Tieghem in the chair.—The Perpetual Secretary announced to the Academy the loss it had sustained by the death of M. Rieggenbach, correspondent in the Section of Mechanics.—Thermogenesis and use of energy by man in raising and lowering his own weight, by M. A. Chauveau. The positive work done by the animal motor is shown by experiment to take from the animal heat an amount quantitatively equal to the mechanical work produced. When the subject does negative work in the calorimeter, the heat produced is much greater than should arise from the normal physiological work of the organism.—On the law of pressures in gun-muzzles, by M. E Vallier. The author applies the formula previously given by him to the discussion of some experiments by M. Zaboudski, and introduces certain simplifications into his original expression.—Hypodermic impregnation in the *Haementaria castata* of Müller (*Placobdella catenigera* of R. Blanchard), by M. A. Kowalevsky.—On the annular nebula in Lyra, from observations made at the Observatory of Toulouse, by MM. Bourget, Montangerand, and Baillaud. The observations show unmistakably that very sensible changes of brightness have taken place in this nebula during the last twenty years.—Observations of $\beta$-Lyræ, made at the Observatory of Lyons, by M. M. Luizet.—On the variable star (D.M. + 12°·3557) of the Algol type, by M. Luizet.—On the methods of M. Loewy for the determination of latitudes, by MM. W. Ebert and J. Perchot.—The variations of the apparent horizon, by M. F. A. Forel. The possible error in the measurement of the position of the true horizon deduced from observation of the apparent horizon, is greater when the air is calm than when it is in motion, and greater than when the air is warmer than the water than the reverse; hence the observations are best taken in the morning.—On the equations of Pfaff, by M. E. O. Lovett.—On certain differential equations, by M. Henri Dulac.—On the changes of state of iron and steel, by M. H. Le Chatelier.—On the electric deformations of solid isotropic dielectrics, by M. Paul Sacerdote.—On the spectra of oscillating discharges, by M. G. A. Hemsalech.—With the oscillating discharges, a particular value for the self-induction of the circuit can be made to give a spectrum almost totally free from air lines, and showing very clearly the characteristic rays of the metals forming the electrodes.—On the isomeric states of chromium acetate: biacid abnormal violet acetate and a green abnormal monoacetate, by M. A. Recoura.—Action of magnesium upon saline solutions, by M. Georges Lemoine. Concentrated solutions of magnesium chloride rapidly disengage hydrogen when treated with magnesium powder, magnesia being simultaneously formed.—On the dissociation of the hexammoniacal cadmium chloride, by MM. W. R. Lang and A. Rigaut.—On the dissociation of mercurdiammonium iodide, by M. Maurice François. The compound of mercuric iodide and ammonia behaves similarly to the ammoniacal silver chlorides, the dissociation pressures showing that an intermediate compound $3HgI_2.4NH_3$ exists.—Action of sodammonium and potassammonium upon selenium, by M. C. Hugot.—On some acetonylacetonates, by MM. G. Urbain and A. Debierne. In the present paper details are given of the iron, manganese, cobalt, chromium, and aluminium compounds.—Action of mineral substances and organic acids upon the variations of resistance and modifications of the system, by MM. Charrin, Guillemonat, and Levaditi.—Immunity and specificity. Remarks on the preceding note, by M. Ch. Bouchard.—On the gluten and nitrogenous material of flour, by M. Balland. As flour grows older, the gluten appears to undergo a change, as it loses its coagulating properties, and is carried away in increasing quantity by washing with water.—Estimation of carbon dioxide at the summit of Mt. Blanc, by M. Maurice de Thierry. Details of estimations of ozone and carbonic acids carried out at Chamonix and Grand Mulets in August and September 1898.

## ENZYMES.

*The Soluble Ferments and Fermentation.* By J. Reynolds Green, Sc.D., F.R.S. Pp. xiv + 480. (Cambridge University Press, 1899.)

PROBABLY no subject in the whole of the vast domain of biology exceeds this in interest, and certainly none transcends it in the importance of its bearings on the doings of the human race. The bread and cheese we eat, the beer and wine we drink, are entirely dependent on these ferments for their preparation; and the same is true of the processes of digestion which render their products assimilable into the plant or animal economy.

Then, have not Pasteur and men who have followed him made clear that the principle of fermentation lies at the root of an enormous class of diseases; aye, and demonstrated the truth of the doctrine by that most cogent of all arguments—experimental production of the disease from the use of the agents, and cure or prevention of it by the employment of the antidotes and therapeutic measures suggested by the scientific inquiry?

The making of jams, the tinning of preserved meats and fruits, the curing of hides and tanning of leather, and a hundred other branches of industry owe their successful pursuit to the intelligent application of the teachings of science; so clearly is this being recognised now, that it is becoming customary to speak of "fermentation industries" as a class. For it must no longer be supposed that brewing is the only fermentation industry; modern discovery in connection with dyeing, the curing of tobacco, the retting of flax, and many departments of agriculture show the necessity of extending the idea. Dr. Green's aim has been to collect all that is known of the study of those remarkable and curious bodies (Enzymes) which can be extracted from the protoplasm of living cells, can be precipitated mechanically from the solutions, and preserved as dry, impalpable powders, and still retain more or less unimpaired their astonishing powers of again bringing about decompositions of sugar, fats, proteids and other organic substances in solutions just as they could in the cell itself or in the waters outside the cell.

These powers are astonishing, because they are manifested so extensively by almost unweighably small quantities of the enzyme, and because they are exerted so smoothly and with such apparent ease and economy on bodies which we know to be very stable, and which can be artificially decomposed in similar ways only by the application of very energetic processes and very wastefully.

For it would seem that the study of fermentation is now the study of enzymes. Even the one sharply contrasted case—alcoholic fermentation—which Pasteur's classical labours appeared to place in a category apart from those of the enzymes, has come into line with the rest since Buchner's discovery that an enzyme-like body can be extracted from the cells of the yeast-plant, and can split up sugar into alcohol and carbon dioxide outside the living cell.

Very few authors have attempted the collection of the huge and ever-increasing mass of information scattered through the various journals devoted to special researches on fermentations, and the student had long been dependent on the now antiquated books of Schutzenberger and Naegeli for his summary of general views on the subject, until, in 1893, the extremely interesting but meagre brochure of Bourquelot came out to tantalise him with its disappointing sketch of recent progress. Now we can claim, from the hands of an English botanist, a comprehensive survey, which, whatever its few faults in detail, covers the enormous area admirably, and brings out the salient points and recent discoveries in a very satisfactory manner.

Until a few years ago, it was generally accepted that Pasteur's doctrine—fermentation is the result of life without oxygen—formed the corner-stone of the whole subject. The gradual recognition of the important parts played by the "soluble ferments," or *enzymes*, which, though their discovery dates from 1814, 1823, 1831, were not much studied before 1870, led to the further view that two categories of fermentation-processes must be distinguished, and the attempt was made by Naegeli and Sachs to uphold the idea that soluble or "unorganised" ferments (enzymes) act differently from "organised" or living ferments—*e.g.* bacteria, yeast-cells, &c.

Apart from other discrepancies, the fact that fermentations occur universally in higher plants and animals, as well as in lower organisms, rendered this view untenable, until the startling discovery by Buchner, in 1897, that a something of the nature of an enzyme can be extracted in water from the yeast-cell, which—outside the yeast-cell and quite independent of it—converts sugar into carbon dioxide and alcohol, may be said to have removed its last prop.

Although Lafar, in his remarkably able summary of the ferment-activity of the lower organisms, restricts the definition of fermentation to "transformations of matter . . . exclusively by the vital action of ferments," understanding by the latter word the living cells themselves, it is evident that we are here confronted with an entirely different definition of fermentation. Having abandoned successively the views that it is a phenomenon of life without oxygen, that it is confined to the protoplasmic activity of lower organisms, that there are two different categories of ferments—organised and unorganised, we are now threatened once more with the generalisation that fermentation is a purely chemical phenomenon due to the peculiar molecular activity of certain bodies formed, it is true, by protoplasm, but acting independently of it: a generalisation supported by Fischer's work on the constitution of the sugars, which he regards as so built up that an enzyme can only attack any particular sugar the molecular symmetry of which is related to its own, much as the wards of a lock can be overcome only by a key with a particular pattern.

Dr. Green gives us a very exhaustive account of the many various enzymes now known, classifying them under the following heads.

(1) Those which transform insoluble carbohydrates, producing soluble sugars—*e.g. Diastase* in germinating seeds and other plant-organs, which attacks starch;

R

*Inulase*, which decomposes inulin ; *Cytase*, which hydrolyses cellulose.

(2) Those which transform more complex sugars into simpler compounds of the same class—*e.g.* *Invertase*, which attacks cane-sugar ; *Glucase*, which splits up maltose, and others.

(3) Those which break up glucosides into some sugar and an aromatic body—*e.g.* *Emulsin*, which decomposes the amygdalin of almonds into sugar and prussic acid ; *Myrosin*, which breaks up the sinigrin of mustard into a sugar and the pungent substance so well known.

(4) Proteolytic enzymes, such as *Pepsin* and *Trypsin*, which decompose insoluble and indigestible proteids into soluble and digestible peptones and other bodies, and play so important a part in digestive processes generally.

(5) The clotting enzymes which bring about coagulations—*e.g.* *Rennet*, so important in converting milk into cheese ; *Thrombase*, the enzyme concerned in the coagulation of blood ; *Pectase*, the chief agent in forming vegetable jellies.

(6) The *Lipases*, concerned in decomposing oils and fats.

(7) The *Oxydases*, a curious class of enzymes recently shown to be active in carrying oxygen and bringing about the oxidation of certain vegetable juices—*e.g.* *Laccase*, concerned in the formation of lacquer varnish.

(8) A number of enzymes as yet unclassified—*e.g.* *Urease*, which induces the formation of ammonium carbonate from urea, and the newly discovered "zymase" of Buchner—the alcohol producing enzyme.

It is, of course, impossible in a review to go far into particulars concerning these numerous forms, of which, moreover, there are many varieties. On reading Dr. Green's admirable and exhaustive account of them, the student will be struck with the prominent position which the study of plants occupies in the elucidation of the properties of enzymes. It has been far too fashionable in this country to regard enzymes and the study of fermentation as if they were in some way specially accredited to the domain of the chemist, whereas inasmuch as any such specialisation can be insisted upon, the study is far more within the domain of the botanist and the physiologist, a fact very clearly brought out in this book ; as are also many of the important bearings of the study on the numerous applications of botanical science in the arts.

Secondly, it is worth remarking, in full view of the industrious and valuable work done by able continental botanists and physiologists, how conspicuous are the researches of English investigators in this department of science during the last few years, denoting a phase of activity on the part of our physiologists and botanists which promises well in the future. The author has collected a long list of authorities, and since he has made the study of fermentations peculiarly his own for some years, we may accept the literature as practically complete. At the same time, in view of the remarks on p. 75, we should have expected some quotation of Mr. Parkin's recent and important paper on the inulins in monocotyledons.

In view of the modernity of the study of enzymes, we can hardly be surprised at the lack of any complete deductive explanation of their action, though one of the most interesting sections of the book is that discussing the various hypotheses raised. Our ignorance of the constitution of enzymes no doubt stands at the bottom of this, and it is not at present clear what is meant by a soluble enzyme or by solution. But the fatal blocks to progress in the study of their constitution so far have been their instability during separation, and the uncertainty as to their purity ; consequently the analyses so far attempted cannot be relied on, and we do not even know of any enzyme that it is proteid in nature. All we can be sure of is that a given watery extract washes out from living protoplasm a something—which we term an enzyme—which is capable of converting enormous masses of some other body—*e.g.* sugar—and can itself be mechanically precipitated, re-dissolved and so on. This precipitate may even be dried and retain its specific powers on re-solution. Whether the precipitate consists principally of the enzyme itself or of some body or bodies to which it is attached, is an unsolved question.

But when active and in solution, it is significant that the properties of an enzyme can be destroyed in a few moments by raising the temperature beyond a (relatively low) maximum, and that the activity rises and falls with a scale of temperature between the limits ; on the other hand, it differs from a living organism in being capable of exerting its specific power in presence of an antiseptic.

In the discussion regarding fermentation as a chemical process, these facts should not be overlooked, and it is as true to-day as it was in Pasteur's time, that you cannot have fermentation without life.

No matter how "dead" an enzyme may be ; no matter whether its remarkable energy consists in surface-actions or in vibrations propagated through the solution, in temporary chemical unions and disunions or in electrical hydrolysis ; and no matter what its chemical analyses may imply as to its proteid nature—the fact must be maintained that enzymes are built up by living protoplasm, and normally exert their best actions in connection with the living cell. In many respects, indeed, they suggest essential bits of the protoplasm, and in many ways remind us that we have not yet done with the physiological or "vital" theory of fermentation, and this will, we think, strike most readers, though perhaps Dr. Green's summing up inclines more to the view that fermentation is a purely chemical process. Not the least important prop to the chemical theory of enzyme-action is furnished by Croft Hill's recent work on the action of maltase or glucase on malt-sugar, and his remarkable discovery that a reversal of the enzyme-action may occur, reminding us of the reversals occurring in certain chemical processes.

Here, however, we must stop. It is not necessary to recommend the perusal of the book to all interested in the subject, since it is indispensable to them, and we will merely conclude by congratulating the Cambridge Press on having added to their admirable series of Natural Science Manuals an eminently successful work on so important and difficult a theme, and the author on having written a treatise cleverly conceived, indus-

triously and ably worked out, and, on the whole, well written. At the same time, it should be pointed out that such a work was especially in need of a good and exhaustive index, and that it is a pity the author did not compile one himself.

## CALCULATION BY ABACUS.

*Traité de Nomographie.* Par Maurice d'Ocagne. Pp. xiv + 480. (Paris: Gauthier-Villars, 1899.)

THIS is a book which ought to make even the ordinary reader appreciate the perennial freshness of mathematics. The method of "Nomography" (X3 of the international catalogue), recent as it is in its more important developments, is based upon a very simple idea which has long been familiar—that of the indexed scale. The ever-recurring problem of applied mathematics is to calculate an unknown numerical quantity from its relation to other quantities that are known. The simplest case is when two quantities $x, y$ are connected by a relation $f(x, y) = 0$ or $y = \phi(x)$. For practical purposes it is convenient to have a permanent record of a large number of corresponding values of $x$ and $y$ so that for any given value of $x$ the approximate value of $y$ may be at once found or obtained by simple interpolation. Three methods are available: the first is that of a numerical table, such as a table of logarithms; the second that of the graph, for instance the curve $f(x, y) = 0$ or $y = \phi(x)$ referred to rectangular coordinates; the third is that of the indexed scale, that is to say a straight line or curve at different points of which the corresponding values of $x$ and $y$ are shown in figures. A familiar example is given by a thermometer with Centigrade and Fahrenheit readings, or by a measuring tape with centimetres marked along one edge and inches along the other.

In this very simple case the advantage of the indexed scale is not very obvious; even here, however, the method combines much of the vividness of the graph with a considerable saving of space. It is when three or more variables are connected by a relation that the great value of the scale method becomes apparent. Suppose, for instance, we have a relation

$$F\{\phi(x), \chi(y), \psi(z), \omega(t)\} = 0$$

where $x$, $y$, $z$, $t$ are the variables and F, $\phi$, $\chi$, $\psi$, $\omega$ are known functions. The essence of the nomographic function consists in first plotting off in a suitable way indexed scales of $\phi(x)$, $\chi(y)$, $\psi(z)$, $\omega(t)$, and then employing a linkage or similar mechanism to associate four corresponding values, $x'$ $y'$, $z'$, $t'$. In the case of two variables $x, y$ the "linkage" consists merely in the juxtaposition of the scales; when a proportion sum is done with a slide-rule, the scales are moved relatively to each other; in most of M. d'Ocagne's illustrations, involving several variables, the scales are either superposed in a two-dimensional grating or a movable linkage is used consisting of a transparent sheet with lines of reference ruled upon it, or a combination of both devices is employed.

Of course a method so elastic leaves ample room for ingenuity in constructing an "abacus," as M. d'Ocagne calls it, suited to any particular problem. The author gives an abundant variety of illustrations, many of great practical importance to the physicist and engineer: it is by studying these, and actually taking readings for himself, that the reader will succeed in appreciating the value of the method. For of this, as of other graphical methods, it may be said that merely reading it up, or understanding its principles in a general way, is of little use as compared with a thorough working knowledge of its application.

At the same time, M. d'Ocagne has done really good service in devoting his final chapter to the general theory. This has, in its way, the same kind of special value as Reuleaux's "Kinematics of Machinery" in relation to the ordinary treatises on mechanism. For in this chapter we have a clear conspectus of the general principles which underlie the construction of *any* abacus; and, what is still more remarkable, all possible varieties of abacus are classified into perfectly definite types which can be expressed by a simple abstract notation. Oddly enough, the enumeration of the different types leads to a difficult problem in the partition of numbers, happily solved by Major MacMahon.

It is not impossible that the human race may ultimately set off against the ravages of warfare the indirect stimulus which it has given to mathematics; nomography, at any rate, has been developed in great measure to meet the demands of civil and military engineering. M. d'Ocagne's numerous bibliographical notes will enable his readers to follow in detail, if they wish, the history of the subject. Pure and applied mathematicians alike will be grateful to him for a work so full of novelty and interest; while its subject-matter, as well as its clearness and simplicity, ought to make it eminently acceptable to the engineer.

G. B. M.

## OUR BOOK SHELF.

*Die Spiele der Menschen.* By Karl Groos. Pp. vi + 538. (Jena: G. Fischer, 1899.)

PROF. GROOS will add by the present volume to the reputation he has already earned by his well-known work on the "Games of Animals." A really comprehensive account, at once sympathetic and intelligent, of the games of both children and adults has long been a desideratum with the psychologist as well as with the anthropologist, and Prof. Groos's new work goes very far indeed towards permanently supplying the want. As is only right and proper, by far the larger part of the book is given up to an exhaustive description of the facts as far as they are known; the "Theory of Play" enunciated in the second part of the treatise can thus be judged by the reader upon a sufficiently wide basis of empirical information. The range and the accuracy of Prof. Groos's knowledge are alike surprising; not only is he a mine of information about the amusements of his own country, but he appears, for instance, as much at home in the English nursery and playground as though he had been brought up amongst us. Almost the only signs of imperfect knowledge of English games to be detected in the whole book are the author's ascription of "Hare and Hounds," in its familiar form, exclusively to America, and his apparent ignorance of the continued vitality of "Hunt the Slipper." As a psychologist Prof. Groos is distinguished by a singular subtlety of discrimination; his account, for instance, of the various elements which enter into the gambler's enjoyment of high play, or, again,

of the combination of "the pleasure of intense stimulus" and the "pleasure of conflict" in our enjoyment of a tragedy, are models of delicate æsthetic analysis. The author's attitude towards the various current theories of "play" is eminently judicious. As he well points out, both the "surplus activity" theory and the "recreation" theory are one-sided, the former doing less than justice to the pastimes of adults, the latter to those of children. His own view that play must be regarded by the biologist primarily as the great educator and perfecter of imperfect instincts has been most nearly approached by Prof. Baldwin. Prof. Groos's treatment of the sociological aspects of "play," both as the child's earliest form of experimentation and as the earliest school of obedience to authority, should prove useful to students of ethics as well as to professed sociologists. The admirable literary style of the book, no less than the interest of its contents, should recommend it to all persons of general culture who care for anthropological studies. A. E. T.

*Physique et Chimie Viticoles.* By A. de Saporta. Pp. iv + 300. (Paris: G. Carré and C. Naud, 1899.)

IN the preface to this book, contributed by M. P. P. Dehérain, the immense importance of the vine culture to France is pointed out, the wine from the department of Hérault alone having in 1897 a value of 212,000,000 francs. The questions of suitability of soil, of manures, of the remedies against the many diseases of the vine, of fermentation, and preservation of wine all depend largely upon simple chemical and physical considerations; hence arises the necessity for such a work as the present, dealing with the physics and chemistry of vine culture and wine production. Of the eight chapters composing the book, the first two are preliminary, giving a very brief outline of the atomic theory and the measuring instruments used in the laboratory. The third chapter deals with the soil, especial attention being directed to the use of various insecticides, and to the causes of vine disease generally residing in the soil. In the third chapter, on account of the importance of the estimation of calcium carbonate in the soil, numerous calcimeters are described, some of considerable and apparently unnecessary complexity, as, for example, the self-registering calcimeter of Houdaille. The description of the properties of manures is lucid, and their analysis is treated in a simple manner. Chapter vi., dealing with the remedies for vine diseases, is, on account of the evident practical knowledge of the author, the most valuable portion of the book. The number of remedies that have been invoked to combat mildew, black rot, chlorosis, phylloxera, and other vine diseases, is so great as to render their classification and intelligent use difficult. Especial attention is here directed to the use of carbon bisulphide, ferrous sulphate, sulphur, copper sulphate and acetate, and mercury salts, the last-named being emphatically condemned in spite of their undoubted efficacy in combating fungoid diseases. The concluding chapters deal briefly with the fermentation of the grape, analysis of the wine, and the diseases to which it is liable. The book will be of great practical service to vine growers.

*Cours Élémentaire de Zoologie.* Par Remy Perrier. Pp. 734. 697 illustrations. (Paris: Masson et Cie., 1899.)

THIS work contains a great deal in brief that is to be found in its predecessor, the author's "Éléments d'Anatomie Comparée," published in 1893. In some respects it may be said to be a "Grundriss" to that volume, but, in contradistinction to it, the Vertebrata are here treated on a greater equality with the Invertebrata, and the order of presentation is more rational and in accordance with precedent. For example, the Chætopod Worms are dealt with before the Arthropods, the inversion of this order being a notorious feature of the "Éléments." Chapter i. is devoted to broad principles and definitions, Chapter ii. to the elements of histology, and Chapter iii. to the classification of the metazoa—177 pp. in all. Tables of affinity and structural relationship are here and there given, and the 565 remaining pages of the work are devoted to a systematic consideration of each of the greater groups of animal forms in an ascending order, the Echinoderms, Rotifers, Polyzoa, and Brachiopods being taken after the Cœlenterates and before the Leeches and Worms. Some of the groups receive but scanty treatment, meagre and wholly insufficient, and throughout the work the author has conspicuously neglected the rendering clear the extremes of modification of the great groups, which we consider should be an indispensable feature of an elementary text-book on organic forms that shall do justice to our present knowledge. In dealing with such an assemblage as the Tunicata, where octoradiate, valved, stalked, and many other well-known forms occur, a great opportunity has in this way been lost, and the same may be said of the author's treatment of the Bryozoa.

The illustrations are for the most part good and clear; some of the new ones are admirable, and we congratulate the author upon such as his aortic arch series (p. 602), which are the most accurate and up to date of any text-book set yet published. They are sure to be popular and reproduced *ad nauseam.* But why that old nightmare the Cuvier's "Chimæra" (Fig. 589), a badly drawn Chimæra with a Callorhynchus tail! Surely the time has come when this and other persistent atrocities of our text-books, which have so long offended, should be condemned.

A really sound elementary treatise on zoology has long been a desideratum, and the present work is the outcome of a commendable attempt to supply the need. Though desperately thin in parts it is up to date in its leading themes, well arranged, and written in a good easy style, and it may be safely recommended as trustworthy so far as it goes.

## *LETTERS TO THE EDITOR.*

### Thermometric Scales for Meteorological Use.

IN the course of some recent work on the meteorology of Ben Nevis, which involved extensive extracting and computing work, I have again had forcibly impressed on me the great advantage which Fahrenheit's thermometer has over that of Celsius for meteorological use, especially in temperate regions.

In chemistry and physics the range of temperature covered is so great that Celsius' scale, which is now universally used, adequately meets every case. The size of the degree and the change of sign at the melting point of ice do not cause any inconvenience in the laboratory. It is otherwise in the meteorological observatory. There the range of temperature dealt with is very restricted, and the Celsius degree is too large, while the change of sign in the middle of the working part of the scale is simply intolerable. The latter peculiarity is the fruitful introducer of error into both the observations and the reductions, and besides it greatly increases the fatigue of both classes of work.

In view of the agitation to abolish the use of Fahrenheit's scale, and to replace it universally by that of Celsius, it may not be inopportune to direct attention to some of the advantages in securing accuracy and in relieving labour which Fahrenheit's scale offers over that of Celsius when used for meteorological purposes.

In tropical countries it matters little whether one scale or the other is used, except that the size of Fahrenheit's degree is much

the more convenient, as the first decimal place is always sufficient. But in Europe and in North America, where the greater number of meteorological observatories is situated, the temperature falls every year below the freezing point of water. In some localities it passes quickly through this point and remains constantly below, often far below it, returning again in the spring and passing as quickly through it again in the beginning of summer, to remain constantly above it until it drops away again in the fall of the year. In such places, where, however, the population affected is limited, the use of Celsius' scale is not open to very much objection. With the exception of a few days in the fall, and again in the spring of the year, the temperatures are either continuously positive or continuously negative; and during one-half of the year the observer reads his thermometer upwards, while during the other half of the year he reads it downwards. When he has got well into the one or the other half of the year, he will make no more errors than those that he is personally liable to under circumstances of no difficulty. But at and near the two dates when the temperature is falling or rising through that of melting ice the case is very different. If the rise or fall is rapid, his task is comparatively easy, and, after a few unavoidable mistakes, he has succeeded in inverting his habit of reading. But, in those parts of Europe and North America which carry nearly the whole of the population, the temperature in winter is frequently oscillating from one side to the other of the melting point of ice. If the observer is compelled to use a thermometer which he must read upwards when the temperature is on one side of that point, and downwards when it is on the other side, and if he may be called on to perform this fatiguing functional inversion several times in one day, it is certain that he will suffer from exhaustion, and that the observations will be affected with error.

Were there no other thermometric scale available but that of Celsius, we should simply have to put up with it, and endure the inconvenience of it; but, when we have another scale, one devised primarily for meteorological observations in the North of Europe, by a philosopher who constructed it with a single eye to its fitness for what it was to be called upon to measure, and when, in addition, this scale is still exclusively used in a large proportion of the meteorological observatories of the world, it seems almost incredible that amongst reasonable people, be they scientific or non-scientific, there should be a powerful agitation to abolish the scale which was devised for its work, which excludes error in so far as it can be excluded, and to replace it by one which, besides other defects, introduces, in the nature of things and of men, *avoidable* errors, the elimination of which is the first preliminary of the scientific treatment of all observations in nature.

Every meteorologist in northern countries who makes use of the data which he collects knows that when his temperatures are expressed in Fahrenheit's degrees, he can discuss them at much less expense both of labour and of money for computing than when they are expressed in Celsius' degrees; yet such is the apprehension of even scientific men when brought face to face with the risk of being ruled "out of fashion," that meteorologists who use Fahrenheit's scale, though they fortunately do not give up its use, seem to be disabled from defending it.

What is this stupefying fashion, and can it not be made our friend?

Fahrenheit lived and died before the decimal cult or the worship of the number ten and its multiples came into vogue; but, whether in obedience to the prophetic instinct of great minds or not, it almost seems as if he had foreseen and was concerned to provide for the weaknesses of those that were to come after him. The reformers of weights and measures during the French revolution rejected every practical consideration, and chose the new fundamental unit, the metre, of the length that it is, because they believed it to be an exact decimal fraction one ten-millionth of the length of the meridian from the pole to the equator. Is it an accident that mercury, which was first used by Fahrenheit for filling thermometers, expands by almost exactly one ten-thousandth of its volume for one Fahrenheit's degree?

Again, how did Fahrenheit devise and develop his thermometric scale? A native of Danzig and living the first half of his life there, he considered that the greatest winter cold which he had experienced in that rigorous climate might, for all the purposes of human life, be accepted as the greatest cold which required to be taken into account. He found that this temperature could be reproduced by a certain mixture of snow and salt. As a higher limit of temperature which on similar grounds he held to be the highest that was humanly important, he took the temperature of the healthy human body, and he subdivided the interval into twenty-four degrees, of which eight, or one-third of the scale, were to be below the melting point of pure ice, and two-thirds or sixteen were to be above it. Fahrenheit very early adopted the melting temperature of pure ice for fixing a definite point on his thermometer, but he recognised no right in that temperature to be called by one numeral more than by another. The length of his degree was one-sixteenth of the thermometric distance between the temperature of melting ice and that of the human body, and the zero of his scale was eight of these degrees below the temperature of melting ice, and not, as is often thought, the temperature of a mixture of ice and common salt or sal-ammoniac. Fahrenheit, as has been said, was the first to use mercury for filling thermometers; and being a very skilful worker, he was able to make thermometers of considerable sensitiveness, on which his degrees occupied too great a length to be conveniently or accurately subdivided by the eye. To remedy this he divided the length of his degree by four, and the temperature from the greatest cold to the greatest heat which were of importance to human life came to be subdivided into 96 degrees.

Had he lived in the following century he would have been able to point out that on his scale the range of temperature within which human beings find continued existence possible is represented by the interval 0 to 100 degrees, and there can be little doubt that this would have secured its general adoption. Its preferential title to the name Centigrade is indisputable. Perhaps this may be an assistance to its rehabilitation as the thermometer of meteorology. J. Y. BUCHANAN.

Cambridge, August 4.

## On the Deduction of Increase-Rates from Physical and other Tables.

THE problem treated by Prof. Everett in your issue of July 20, p. 271, allows a somewhat simpler solution. Take the example given by Prof. Everett. To find the value of $\frac{dp}{d\theta}$ at the temperature 105°, we have only to consider the columns for $\Delta p$, $\Delta^3 p$, $\Delta^5 p$, &c. In each of these columns there are two numbers, one just above and one just below the horizontal line, corresponding to the value $\theta = 105°$. In the column for $\Delta p$, for instance, these two numbers are 408 and 470, in the column for $\Delta^3 p$ they are 5 and 8. If now $m_1$, $m_3$, $m_5$, &c., are the means of each of these two numbers, so that in this case $m_1 = 439$, $m_3 = 6.5$, we have:

$$\frac{hdp}{d\theta} = m_1 - \frac{m_3}{2.3} + \frac{m_5}{2.3.4.5} 2^2 - \frac{m_7}{2.3.4.5.6.7} 2^2 3^2 + \ldots$$

If $p$ be capable of being expressed in the form $A + B\theta + C\theta^2$ only the first term $m_1$ is required; if

$$p = A + B\theta + C\theta^2 + D\theta^3 + E\theta^4$$

only the first two terms $m_1 - \frac{m_3}{2.3}$ are required, and so forth. In these cases the solution is exact, whereas in general the method gives only approximations closer and closer the more terms are added.

The difference between my solution of the problem and Prof. Everett's is only formal. It may readily be seen that in Prof. Everett's notation

$$2m_1 = d_1 + u_1,\ 2m_3 = d_2 - u_2,\ 2m_5 = (d_3 + u_3) - (d_2 - u_2),$$

which makes his equations special cases of my expression for $\frac{hdp}{d\theta}$. The proof of my expression may be given by the calculus of finite differences. For simplicity let us write $x = \theta - 105°$, and let us develop the function $p$ in the form:

$$p = a_0 + a_1 x + \frac{a_2}{2} x(x-h) + \frac{a_3}{2.3}(x+h)x(x-h) + \ldots$$

General terms:

$$\frac{a_{2n}}{2.3.4\ldots 2n}(x+(n-1)h)\ldots x \ldots (x-nh)$$

$$+ \frac{a_{2n+1}}{2.3.4\ldots 2n+1}(x+nh)\ldots x \ldots (x-nh)$$

By the calculus of finite differences we obtain :

$$\frac{\Delta p}{h}=\frac{p(x+h)-p(x)}{h}=a_1+a_2x+\frac{a_3}{2}(x+h)x+\frac{a_4}{2.3}(x+h)x(x-h)+\ldots$$

and

$$\frac{\Delta^2 p}{h^2}=a_2+a_3(x+h)+\frac{a_4}{2}(x+h)x+\frac{a_5}{2.3}(x+2h)(x+h)x+\ \ldots$$

Therefore :

$$ha_1=\Delta p \text{ for } x=0 \text{ and } h^2a_2=\Delta^2 p \text{ for } x=-h$$

By proceeding in the same way we find $h^{2v}a_{2v}=\Delta^{2v}p$ for $x=-vh$ and $h^{2v+1}a_{2v+1}=\Delta^{2v+1}p$ for $x=-vh$.

The value of $\Delta^{2v}p$ for $x=-vh$ is the number in the column for $\Delta^{2v}p$, which stands in the horizontal line corresponding to the stated value of $\theta$ (105 in our case), while the value of $\Delta^{2v+1}p$ for $x=-vh$ is the number in the next column just below this line. The mean of this number and the one above it we have before denoted by $m_{2v+1}$ ; we now add the notation $m_{2v}$ for the value of $\Delta^{2v}p$ for $x=-vh$. As $m_{2v+2}$ is the difference of the two numbers, whose mean is $m_{2v+1}$, we can write $m_{2v+1}+\frac{1}{2}m_{2v+2}$ instead of the value of $\Delta^{2v+1}p$ for $x=-vh$.

We have therefore :

$$a_{2v}=m_{2v}h^{-2v}$$

and

$$a_{2v+1}=(m_{2v+1}+\tfrac{1}{2}m_{2v+2})h^{-2v}.$$

Substituting these values in the expression for $p$ we have :

$$p=a_0+(m_1+\tfrac{1}{2}m_2)\frac{x}{h}+\frac{m_2}{2}\frac{x(x-h)}{h^2}$$
$$+\frac{1}{2.3}(m_3+\tfrac{1}{2}m_4)\frac{(x+h)x(x-h)}{h^3}+\ \ldots$$

General terms :

$$\frac{1}{2.3\ \ldots\ 2v+1}(m_{2v+1}+\tfrac{1}{2}m_{2v+2})(x+vh)\ \ldots x \ldots\ (x-vh)h^{2v-1}$$
$$+\frac{1}{2.3\ \ldots\ 2v+2}m_{2v+2}(x+vh)\ \ldots\ x\ \ldots\ (x-vh)$$
$$(x-(v+1))h^{-2v-2}.$$

To find the value of $\frac{dp}{d\theta}$ we now need only differentiate according to $x$ and make $x$ equal zero.

Thus we obtain :

$$h\frac{dp}{d\theta}=(m_1+\tfrac{1}{2}m_2)-\frac{m_2}{2}-\frac{1}{2.3}(m_3+\tfrac{1}{2}m_4)+\frac{1}{2.3}\frac{m_4}{2}+\ \ldots$$

General terms :

$$\frac{(-1)^v}{2.3\ \ldots\ 2v+1}(m_{2v+1}+\tfrac{1}{2}m_{2v+2})2^2\,.\,3^2\ \ldots\ v^2$$
$$+\frac{(-1)^{v+1}}{2.3\ \ldots\ 2v+2}m_{2v+2}\,.\,(v+1)\,.\,2^2\,.\,3^2\ \ldots\ v^2;$$

or by contracting two consecutive terms :

$$h\frac{dp}{d\theta}=m_1-\frac{1}{2\,.\,3}m_3+\frac{1}{2\,.\,3\,.\,4\,.\,5}m_5\,.\,2^2-\ \ldots$$

The second differential coefficient is found in a similar way. It is only necessary to observe that the second differential coefficient of $(x+vh)\ \ldots\ x\ \ldots\ (x-vh)$ vanishes for $x=0$ and that of $(x+vh)\ \ldots\ x\ \ldots\ (x-(v+1)h)$ is equal to $2\,.\,(-1)^v\,.\,2^2\,.\,3^2\ \ldots\ v^2h^{-2v}$. Therefore we obtain

$$h^2\frac{d^2p}{d\theta^2}=m_2-\frac{2}{2\,.\,3\,.\,4}m_4+\frac{2}{2\,.\,3\,.\,4\,.\,5\,.\,6}\,.\,2^2\,.\,m_6-\ \ldots$$

General term :

$$\pm\frac{2}{2\,.\,3\,.\,4\ \ldots\ 2v+2}2^2\,.\,3^2\ \ldots\ v^2\,.\,m_{2v+2}.$$

Hannover, Technische Hochschule. C. RUNGE.

PROF. RUNGE'S proof is longer and more difficult than mine ; but his result is in simpler shape, and possesses the great merit of giving the successive approximations as the terms of a regular series. J. D. EVERETT.

22 Earl's Court Square, July 28.

## The So-called "Thunder"-storm.—Prevalence of Anticyclones.

IT must have occurred to others besides myself how very absurd it is to designate a meteorological phenomenon by the least important of its characteristics, viz. the noise it makes. We never speak of a hail-storm as a "rattle"-storm, or a shower of rain as a "patter"-storm ; why then should we call an electrical disturbance a "thunder"-storm ? Thunder, though no doubt terrifying to savages and children and old ladies (one or two of whom have, I believe, been killed by the fright of it), and though of some interest as an acoustic phenomenon, is absolutely the most trivial of the accompaniments of an electrical discharge.

It would seem hopeless to eradicate the childish term entirely from popular language, but surely in the scientific reports and forecasts issued by the Meteorological Office, and in scientific literature generally, the term "electric storm" (or disturbance) might replace "thunderstorm."

With regard to the late prevalence and persistence of anticyclonic conditions over the centre and south of our islands, I wish to suggest that it may be connected with the unusual extension southwards of the Polar ice-pack this summer. I saw it stated about a month ago that even Spitsbergen was then surrounded by ice, most of the fiords being quite inaccessible. When I was there in July 1896 we could only just see the blink of the pack in the north horizon.

Now, it is an ascertained and easily intelligible fact that areas of cold (water or ice) on the earth's surface have a tendency to cause the formation of areas of high pressure or dense air in the atmosphere above them. The result would be, not only a prevalence of anticyclones in high latitudes over the North Atlantic, but also the persistent extension of the northern edge of the great "Atlantic anticyclone" over the south and centre of England (attracted, as it were, by the high pressure in the north) ; so that cyclones which usually strike the south-west of Ireland or the coast of Cornwall have been "fended off" to the north of Scotland, with the result of heat and drought over England.

I only put this forward as a suggestion, and I should be glad if any of your Icelandic or Norwegian readers would supply details of the position of the Polar ice-pack, temperature of the sea in the North Atlantic, &c., for I have learnt to mistrust all statements appearing in those interesting, and often sensational, works of fiction—the daily papers. METEOR.

August 12.

## Scoring at Rifle Matches.

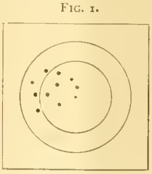
WHILE the Bisley meeting is still fresh in the memory of those interested in rifle shooting, it seems worth while to call attention to the rather unsatisfactory nature of the method of scoring now in general use.

What brings the matter into special prominence is the large number of "best possibles" always made in recent years.

With a satisfactory system of scoring such a phrase ought only to apply when every shot passes through the same hole in the centre of the bull's-eye.

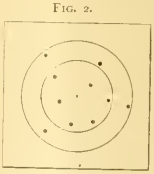
The present practice, however, gives the same number of marks to shooting of widely differing merit, and this must always be the case as long as the result is made to depend on the distance of each shot from the centre of the target, irrespective of the distance of the shots from one another (see Figs. 1 and 2).

FIG. 1.



Ordinary score 46.
By moment of inertia 24·5.

FIG. 2.



Ordinary score 46.
By moment of inertia 18.

The merit of any series of shots really depends on two elements, namely, the distance of the average direction of the whole series from the centre of the target and the compactness with which the individual shots are grouped about that direction.

The importance to be assigned to each of these elements may vary with the object for which the shooting is undertaken, but a knowledge of both is essential in estimating its quality.

If the object be to get all the shot as near the centre of the target as may be, the same importance should be attached to close grouping as to the mean direction, as will be shown further on.

Since any practical method of scoring must be rapid and easily understood by people who are not mathematical, it would probably be asking too much if it were proposed to treat each result in an accurate manner, simple though the required arithmetic is; but some modification of the accurate method could probably be made sufficiently simple for general use, which would give a much truer estimate of the goodness of the shooting than that now in use.

The accurate plan of estimating the value of any series of shots consists, in mathematical language, of finding the distance of the centre of gravity of the group from the centre of the target, and taking the radius of gyration of the group about its centre of gravity. The goodness of the shooting will then be measured by the reciprocal of the sum of the squares of these quantities, each multiplied by a constant, and it will presently be shown that if, as in an ordinary match, the object is to hit the centre of the target, these constants are equal.

A convenient way of finding the centre of gravity and radius of gyration is to have the target divided into 100 squares by eleven vertical and eleven horizontal lines (see Fig. 4), the position of the shot being recorded by naming the square through which it passes; (for instance, a shot in the fourth vertical row and fifth horizontal row would be recorded as 4·5).

If we call the number of the vertical row $x$, and the number of the horizontal row $y$, very simple algebra will prove—in fact, it is obvious—that for a series of $n$ shots the coordinates $(h \,.\, k)$ of square containing the centre of gravity of the shots will be

$$h = \Sigma x/n \quad k = \Sigma y/n,$$

where $\Sigma x$ denotes the sum of all the $x$'s, and $\Sigma y$ denotes the sum of all the $y$'s.

Since the score does not record the position of an individual shot with greater accuracy than the width of a single square this is equivalent to the assumption that each shot passes through the centre of the square it hits, and that the origin of the coordinates is in the centre of the square at 0 (off the target) (see Fig. 4).

Thus the coordinates of the centre of the target will be

$$x = 5{\cdot}5 \quad y = 5{\cdot}5,$$

and the distance of the centre of gravity from the centre of the target is

$$R = \sqrt{(\Sigma x/n - 5{\cdot}5)^2 + (\Sigma y/n - 5{\cdot}5)^2}.$$

The radius of gyration of the group about an axis normal to the plane of the target, and passing through the centre of gravity is

$$\rho = \sqrt{\Sigma x^2/n - h^2 + \Sigma y^2/n - k^2}.$$

To examine the relative importance of the closeness of the shots to one another and the distance of their mean from the centre of gravity, consider the effect of slightly varying each of the quantities R and $\rho$.

The question to be answered is: "If of two groups one is represented by R and $\rho$, and the other by $R + dR$ and $\rho - d\rho$, which gives evidence of the best shooting?"

In Fig. 3 let C be the centre of the target, and G the centre of gravity of the group, and P Q R a circle described with radius $\rho$ about G, so that $CG = R$, $GP = \rho$; then if $CGP = \theta$, the distance $(r)$ of P from C is

$$r = \sqrt{R^2 - 2R\rho\cos\theta + \rho^2},$$

differentiating with respect to R and $\rho$, we have

$$\frac{dr}{dR} \Big/ \frac{dr}{d\rho} = -\frac{\rho - R\cos\theta}{R - \rho\cos\theta};$$

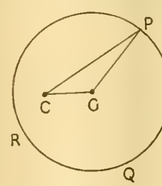


FIG. 3.

and integrating this with respect to $\theta$ from $\pi$ to 0 we have for the relative mean values of $dr$, caused respectively by alterations of $dR$ and $-d\rho$ in the values of R and $\rho$,

$$\left\{ \int_0^\pi \frac{dr}{dR} \Big/ \int_0^\pi \frac{dr}{d\rho} \right\} d\theta = \frac{\rho}{R}.$$

If the two groups are equally good, the mean value of $dR$ must be equal to minus the mean value of $d\rho$.

This leads to a simple relation between R and $\rho$, viz. $R^2 + \rho^2$ = constant. Thus any group of shots for which the sum of the squares of the mean distance of the group from the centre and its radius of gyration is constant is equally good.

This may be stated more concisely by saying that when the object is to hit the centre of the target, the merit of any series of shots is inversely proportional to its moment of inertia of the group about the centre of the target.

If for convenience it is decided to make the score 100 when the moment is unity, the worth of any given series will be represented by

$$\frac{100}{R^2 + \rho^2}.$$

I give below an actual target with the results analysed in the way described.

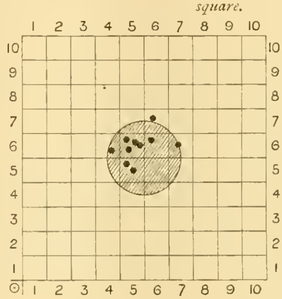
If a slide rule is used, the arithmetic takes about five minutes.

I do not for a moment suppose that such an analysis would be practicable at ordinary rifle matches, but it does seem possible that coordinate targets might become popular, and some simple way devised of using the more precise information they would afford.

As far as finding the moment of inertia of the group about the centre of the target is concerned, this might be done more simply by the use of polar coordinates, only the mean square of the distance from the centre being wanted for that purpose; but the Cartesian coordinates are more convenient when the closeness of the grouping has to be considered.

EXAMPLE.

*Coordinate Target. Ten shots at* 100 *yards. Target* 10 *inches square.*



| Shot | Score X | Score Y |
|---|---|---|
| 1 | 5 | 6 |
| 2 | 4 | 6 |
| 3 | 5 | 5 |
| 4 | 5 | 6 |
| 5 | 6 | 7 |
| 6 | 7 | 6 |
| 7 | 5 | 6 |
| 8 | 6 | 6 |
| 9 | 5 | 6 |
| 10 | 5 | 5 |

FIG. 4.

To analyse the score it is convenient to arrange the results in the following form; $p$ and $q$ being the number of shots on each vertical and horizontal row.

| $x$ | $p$ | $px$ | $y$ | $q$ | $qy$ | $px^2$ | $qy^2$ |
|---|---|---|---|---|---|---|---|
| 1 | — | — | 1 | — | — | — | — |
| 2 | — | — | 2 | — | — | — | — |
| 3 | — | — | 3 | — | — | — | — |
| 4 | 1 | 4 | 4 | — | — | 16 | — |
| 5 | 6 | 30 | 5 | 2 | 10 | 150 | 50 |
| 6 | 2 | 12 | 6 | 7 | 42 | 72 | 252 |
| 7 | 1 | 7 | 7 | 1 | 7 | 49 | 49 |
| 8 | — | — | 8 | — | — | — | — |
| 9 | — | — | 9 | — | — | — | — |
| 10 | — | — | 10 | — | — | — | — |
| | | $\frac{\Sigma x}{n}$ 5·3 | | | $\frac{\Sigma y}{n}$ 5·9 | $\frac{\Sigma x^2}{n}$ 28·7 | $\frac{\Sigma y^2}{n}$ 35·1 |
| | | $\frac{\Sigma x}{n} - h =$ 5·5 | | | $\frac{\Sigma y}{n} - k =$ 5·5 | $\left(\frac{\Sigma x}{n}\right)^2$ 28·1 | $\left(\frac{\Sigma y}{n}\right)^2$ 34·7 |
| | | −·2 | | | ·4 | ·6 | ·4 |
| | | | | | | | .6 |
| | | $R^2 = (\cdot 2)^2 + (\cdot 4)^2 = \cdot 2$ | | | | | $\rho^2 =$ 1·0 |

This counts $\frac{100}{1 + 2{\cdot}2}$ or 84.

A. MALLOCK.

## ON SPECTRUM SERIES.[1]

WE have now, I trust, obtained a general idea of inorganic evolution so far as stratigraphic geology is concerned. You may remember that I pointed out that the evidence for organic evolution not only depended upon the various vegetable and animal forms which had been found in the various strata of the earth's crust from the pre-Laurentian up to the Recent times, but that the science of embryology had also been brought into play, and that a succession of forms in the individual was there to attest the general line of descent. To-night we have to deal with the spectroscope and the motions of the smallest units of inorganic matter which we can get at, and to compare the results obtained in this way with some of those that the biologist has arrived at by means of the microscopic examination of the smallest unit forms that he can observe. From the spectrum point of view, this inquiry is included in the word "series." In the study of series of lines in different spectra, we are on the same ground plan as the biologist is when he is studying what he calls cytology, or the laws of cells.

To explain what is meant by "series" I will refer to one or two photographs of what are termed fluted spectra. You will observe that such a spectrum is perfectly rhythmic from end to end. The whole of a fluting may be regarded as a unit; it is generally strongest towards the right or the red end of the spectrum, its elements gradually becoming dimmer as we approach the violet end. But a fluting is generally more than this; it is built up of subsidiary flutings. Each of the subdivisions of it is in itself an almost exact representation in the small of what the whole thing is in the great; so that we have the conceptions of a simple fluting and a compound fluting. The compound flutings are well represented in the flu tings of carbon. It is by means of such photographs that t he existence of carbon in the sun has been determined. Each of the finer lines in one of the first elements of the compound fluting has a dark line corresponding with it among the Fraunhofer lines. In the case of the spectrum of nitrogen we get the same exquisite rhythm, the same intensification of the series of lines towards the red, and the same division of some of the larger flutings into smaller divisions; so that, as I said before, we have to consider flutings really as compound and not as simple phenomena. When we leave these flutings and study an ordinary line spectrum, in a great many cases all rhythm seems to have disappeared. There is apparently no law and no order. Let us take the lines seen when we expose the gases obtained from the mineral cleveite to the action of an electric current.[1] We observe that all rhythm has gone, and there seems to be a very irregular distribution; but when we come to sort those lines out into series, we find that there is just the same exquisite order that we get in the case of the flutings. You notice in the photograph all the lines higgledy-piggledy, the next photograph will show that they have all been resolved into two sets of three series which very much resemble those that we saw before; that is to say, they gradually get nearer together towards the violet, and they all get stronger towards the red. We have then two constituents of the cleveite gases, asterium and helium, and we find that their irregular line spectra when analysed into these series are translated into a wonderful order. I suggested many years ago that the lines in the ordinary line spectrum of a substance may really be remnants of compound flutings, and such inquiries as those that I have to refer to to-night really seem to justify that suggestion. Very well, then, we arrive at the fact that the term "series" is one employed to related lines. It is impossible to suppose that these wonderful rhythmic series of lines are not related in some way to each other, and that being so we have to study their wave-lengths, that is, their positions in the case of any one element; and not only so, but to see if any relation exists between the lines of different elements.

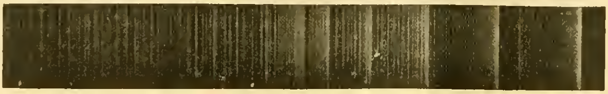


FIG. 1.—Compound flutings of carbon.

FIG. 2.—Simple flutings of nitrogen.

The history of this quite modern inquiry is not very long, but short as it is I only propose to refer to it in the briefest possible manner.

The first attempt to discover regularities in the lines of spectra was made by Lecoq de Boisbaudran,[2] who investigated the spectrum of nitrogen. The conclusions he arrived at suggested that the luminiferous vibrations of the molecules could be compared with the laws of sound, but as these were not based on wave-length determinations of sufficient accuracy, and also were not confirmed by Thalén, no great weight could be attached to the result.

Stoney,[3] who followed up these investigations, was more successful; he showed that the hydrogen lines C, F, and *h* were connected by the relationship 20 : 27 : 32.

Several other workers—Reynolds, Soret, &c.—took the subject up, but it was left for the more thorough work of Schuster[4] to show that this theory could no

[1] A Lecture to Working Men delivered at the Museum of Practical Geology, on May 1, by Prof. Sir Norman Lockyer, K.C.B., F.R.S.

[1] It has always been customary with me in reproducing spectra in the form of illustrations to show the red end of the spectrum on the right hand side and the violet end on the left. As most of the workers on "series" have adopted the opposite way, I propose *in this lecture* to depart from my usual custom and place the red in series spectra on the left, so that all the series illustrations may be comparable *inter se*.

[4] Brit. Assoc. Report, 1880; *Proc. R.S.* (1881), 31, 337.

longer be considered as expressing the law connecting the mutual relationships between the wave-lengths of lines in a spectrum.

Liveing and Dewar[1] next called attention to the fact that the distance between two consecutive lines of these groupings decreases with diminishing wave-lengths, so that eventually the lines asymptotically approach a limit. "Harmonic" was the term they used to express such a series of similar groups of lines.

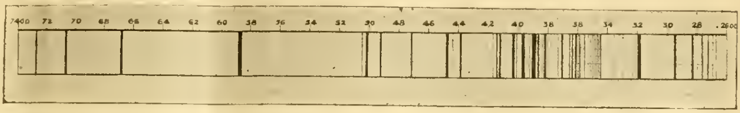

FIG. 3.—Spectrum of the Cleveite gases.

It was, however, the work of Balmer which gave the subject the impetus by which it has of late years made great progress.

Balmer[2] published a formula by which the positions of the hydrogen lines could be calculated with wonderful accuracy. The formula is as follows :—

$$\lambda = A \frac{n^2}{n^2 - 4},$$

in which $\lambda$ is the wave-length in vacuo of the line to be calculated, A a constant common for all the lines, and $n$ one of a series of numbers from 3 to 15.

The constant A, according to Cornu's measurements, is 3645·42 Ångstrom units, or, using Ames' more correct value, 3647·20 Ångstrom units.

Simultaneously with Balmer's discovery, Cornu[3] pointed out that the lines of aluminium and thallium, which are readily reversible, bear a definite relation to those of hydrogen, while at a later date Deslandres[4] published a formula from which could be calculated the wave-lengths of the lines composing the bands of numerous elements.

The above brief history brings us down to the year 1887, in which Kayser and Runge[5] began their series of minute investigations dealing with a great number of elements. It was also about this time that Rydberg[6] commenced to take up the subject.

I will state generally the ground over which their work has extended. They have attacked the question mathematically from different standpoints. In the following table I give the formula employed by Kayser and Runge, and that employed by Rydberg.

*Formulae for Calculating Series.*

| Kayser and Runge | Rydberg. |
|---|---|
| $\frac{1}{\lambda} = A + Bn^{-2} + Cn^{-4}$ | $n = n_0 - \frac{N_0}{(m+\mu)^2}$ |
| where | where |
| $\lambda$ = wave-length | $n$ = wave frequency |
| (or $\frac{1}{\lambda}$ = wave frequency) | $m = 1, 2, 3, \ldots$ |
| $n = 3, 4, 5, \ldots$ | $N_0 = 109721·6$ (a constant applicable to all series of every element) |
| A, B, C = constants calculated for each series. | $n_0$, $\mu$ = characteristic constants varying with each series. |
| The constants for the principal series are different from those used in the subordinate series. | In the above formula, when $m = \infty$, $n = n_0$; or $n_0$ is the limit which the number of waves $n$ approaches when $m$ is infinite. |
| For sub-series of Na, K, Rb, Cs, Cu, Ag, Al, In, and Tl, the constants B and C are identical. For all series the constant B does not vary by more than 22 per cent. This constant B corresponds to Rydberg's $N_0$. | The value of $N_0$ is assumed by Rydberg to be constant, as it varies only slightly, and this variation may be due to uncertain data. |

You will see that they are not by any means identical, but both deal with wave frequency, that is to say, the number of waves in a given unit of length. Then they employ a certain sign, $n$, to represent the successive integers which have to be used to define certain of their terms, and in addition to this we get certain constants which are calculated for each series. The most interesting consideration from this point of view is that Rydberg found that there was one constant which he could use in order to search for the series of lines in the spectra of all the chemical elements with which he worked. There was no common constant similar

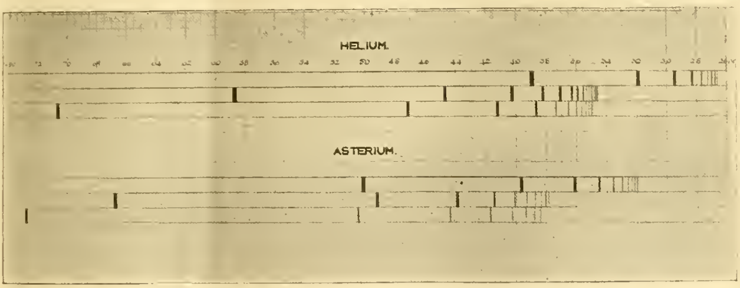

FIG. 4.—Spectrum of the Cleveite gases sorted out into six regular series.

2 *Wied. Ann* (1885), 25, 80.
3 *Comptes rendus* (1885), 100, 1181.
4 *Ibid.* (1886), 103, 375 ; (1887), 104, 972.
5 "Ueber die Spectren der Elemente" (*Abhandlungen d. K. Akad. Berlin*, 1880, 1889, 1890, 1891, 1892, 1893.
6 *Svenska Vetenskap. Akad. Handlingar*, Stockholm (1890), 23, No. 11 ; *Wied. Annalen* (1893), 50, 629 ; (1894), 52, 119.

to this used by Kayser and Runge, but they found that some of their constants varied little from element to element. In that way they not only obtained the first term of a series, but the whole series throughout the entire length of the spectrum, and where observations had been made in the case of the different elements they could of course check their calculations by the actual observations so made, and see how the theory seemed to be justified as the work was extended. The first line in a series must be considered to be comparable to a fundamental note in music. It represents really the longest light wave in the same way that the fundamental note in music represents the longest sound wave. Both series of results, obtained in the way I have described by Kayser and Runge and by Rydberg, show us that, in many cases, we may be almost certain to obtain from the higgledy-piggledy arrangement of the lines in the spectrum of any one substance two or three beautiful regular series like those that I have already shown you in the case of helium and asterium. There is a little difference in the nomenclature employed by the investigators to whom I have referred, as shown in the annexed table.

*Series Nomenclature.*

| Intensity. | Kayser and Runge. | Rydberg. |
|---|---|---|
| Strongest ... | ... Principal series | Principal series |
| Weaker ... | ... 1st subordinate series | Nebulous series |
| Weakest ... | ... 2nd subordinate series | Sharp series |

The strongest lines which they observed at the temperatures they worked with, they put into what they call a "principal series," and then the weaker lines were distributed among other two series. Kayser and Runge called them the "first-" and "second-subordinate" series; Rydberg calls them the "nebulous-series" and the "sharp-series." It is important to remember this in case you come across any reference to these matters, in order that you may see what the exact equivalent is. The lines of the principal series almost always reverse themselves very easily indeed—that is to say, that the absorption is indicated by them more readily than it is by the other lines. Then, when we come to the second subordinate or sharp series, it is found that these sometimes broaden out towards the red end of the spectrum.

This work, of course, has required considerable investigation; the first attempts were not quite satisfactory, because the observations on which it was based had not been of sufficient accuracy. With greater dispersion it has been found that some of the lines which were supposed at first to be single are really double; so that it is quite usual now when we consider this question of series to suppose that in some cases the series are composed of single lines, in other cases of doubles, and in other cases of triplets; and it was at first, indeed, imagined that in these differences we were face to face with a very important physical difference between the various elements, but Rydberg has suggested that possibly after all it may be a difference merely in the seeing.

He says:[1]

"The difference between the doubles and triplets is only relative. This opinion is confirmed by the fact that the triplets appear often in the form of doubles, the most refrangible component not having sufficient intensity to become visible. Further, the relative intensity of the components of the doubles seems equal to that of the two less refrangible components of the triplets.

"For these reasons I have dared to propose the hypothesis that the two kinds of component rays are of the same order, or that the doubles are only triplets of which the most refrangible component is too feeble to be seen, or has perhaps the absolute value of zero. . . ."

[1] *Kon. Sv. Vet. Ak. Hand.*, vol. 23, ii. p. 135.

If the lines are more difficult to see, and if the sub-series of lines get stronger towards either the red end or the blue end, then we are more likely to see one line than two, and more likely to see two lines than three.

I have already referred to the many years old suggestion that a line is a remnant of a fluting. If you could see the whole fluting, you would see what is represented in the upper horizon of the diagram; if you

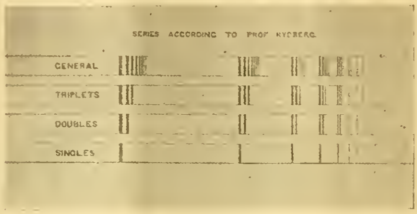

FIG. 5.—Diagram illustrating Rydberg's idea of the appearance of triplets, doubles, &c.

could not see the whole of it, you would get what is represented in the second horizon, that is to say, a triplet. If the third line were very difficult of observation you would only see a doublet, and if the inside line were weaker than the other you would only see a single line.

| Single lines | | Doubles | | Triplets | |
|---|---|---|---|---|---|
| Principal series | Subordinate series | Principal series | Subordinate series | Principal series | Subordinate series |
| Helium | | | Helium | Oxygen | Oxygen |
| Asterium | Asterium | Hydrogen (?) | Hydrogen | Sulphur | Sulphur |
| | | Lithium (?) | Lithium (?) | Selenium | Selenium |
| | | Sodium | Sodium | | Magnesium |
| | | Potassium | Potassium | | Calcium |
| | | Rubidium | | | Strontium |
| | | Cobalt | | | Zinc |
| | | | Copper | | Cadmium |
| | | | Silver | | Mercury |
| | | | Aluminium | | |
| | | | Indium | | |
| | | | Thallium | | |

There is only a very small number of the chemical elements which give us single lines; in the principal series, so far, we only know of helium and asterium: in the subordinate series we only know of asterium. The number of doubles, you will observe, is very much greater, but it is not so great in relation to the principal series as it is in the case of the subordinate series; but although we have nine elements giving us triplets in the subordinate series, we have only three which give them in the principal series.

*(To be continued.)*

## THE DOVER MEETING OF THE BRITISH ASSOCIATION.

THE final arrangements for this year's meeting are now sufficiently completed for a fairly accurate forecast to be made. Whether the meeting will be large or small it is still too early to judge, but whether large or small it will certainly be a very interesting one. As to accommodation in the town, there is little doubt but that at the time of meeting ample accommodation will be available, though the committee have had great difficulties in inducing hotel keepers and lodging-house owners to

reserve rooms for members of the Association, and have only partially succeeded. Dover being a sea-side resort, there has been a natural dislike on the part of owners of hotels and lodgings to offer to disturb those visitors who may possibly have come for a longer stay for the sake of members of the Association who may only wish to spend a week or so. There will, however, be accommodation available in Deal, Canterbury and Folkestone for those who cannot find rooms in Dover. It will be well, however, that intending visitors to the Dover Meeting should inform the local secretaries (E. Wollaston Knocker, C.B., and W. H. Pendlebury, M.A., Castle Hill House, Dover) of their intention, so that approximately the amount of extra accommodation may be known.

It has been usually the case that the secretaries of the various sections are accommodated at the same hotel to facilitate sectional arrangements. This year the Hospitality Committee has been able to arrange with the Head Masters and House Masters of Dover College to entertain the secretaries in the various boarding houses. Unfortunately, the accommodation is limited to the rooms usually occupied by the boys (each of whom has a separate bedroom to himself), so that it is impossible to take in secretaries accompanied by their wives. There will be a few other guests entertained by the Local Committee under the same conditions. The Masters of the various houses will act as hosts on behalf of the Hospitality Committee, and will look after the comfort of their guests. The College Masters will also give the first of the larger garden parties on Thursday, September 14. The Rev. J. N. Bacon has kindly undertaken to make a balloon ascent with objects similar to those which induced him to make an ascent at the Clifton College garden party. The situation of Dover with regard to the sea will doubtless add to the interest of such an ascent.

Lord Northbourne and Lord George Hamilton have kindly consented to allow members of the Association to inspect Betteshanger Park and Deal Castle respectively.

Owing to the fact that two of the days usually given up to excursions are required for the visit of the French Association to Dover and the return visit of the British Association to Boulogne, the number of excursions arranged for will be smaller than usual. The geologists and anthropologists have arranged a number of smaller excursions for the afternoons as usual, and these will, of course, not be interfered with. On the last day of the meeting (Wednesday) the Association is invited by the Dean and Chapter and Mayor and Corporation of Canterbury to pay a visit to that city to meet 200 members of the French Association, who will have previously been entertained to luncheon there. The Mayor and Corporation will entertain the British Association to tea. On the following day (Thursday) an excursion has been arranged to Rochester and Chatham Dockyard for those who do not care to go over to Boulogne. An opportunity will be given to visit the Agricultural College at Wye, near Ashford, which has been so successfully started by the County Councils of Kent and Surrey. The Principal, Mr. A. D. Hall, has invited members of the Association to pay the College a visit and inspect the experimental stations. It may be well to recall the fact that Wye College is especially included in the new University of London, though considerably outside the limit. For those members of the Association who visit Boulogne a most interesting programme has been arranged on the lines laid down in a former article (p. 181). The luncheon will be given by the civic authorities. The French Government has taken a great amount of interest in the gathering, and it is very likely that some prominent French statesman will attend to welcome the British Association in the name of the Government. In such case it is very likely that a similar compliment will be paid to the French Association on their visit to Dover. The French Government has also given instructions to the various Mayors and Prefects of the districts, through which the British Association will pass, in the five days' excursion at the conclusion of the meeting, to take official notice of the tour. The motor-car exhibition arranged by the Mayor of Dover for the Tuesday afternoon has been declared by the Board of Trade an international exhibition, so that no patents will be invalidated by premature disclosure at the Dover show. The French Association intends to give a considerable amount of attention to the automobile.

The Mayor of Dover will give a conversazione in the Town Hall and a garden party in the Connaught Park in addition to the reception at the motor-car exhibition.

The programme of local arrangements will be completed in a few days, and it will then be possible to make a fuller statement of the entertainments prepared for those members of the British Association who may visit Dover.

W. H. PENDLEBURY.

## "*THE WEST INDIAN BULLETIN.*"

IT was on August 2 of last year that Mr. Chamberlain announced in the House of Commons the decision of the Government, based on the recommendations of the West India Royal Commissioners, to create a special Department of Agriculture for the distressed Colonies, to be presided over by Dr. Morris, of Kew Gardens, who had acted as scientific adviser to the Commissioners. Immediately the proposals were sanctioned by Parliament, active steps were taken to vigorously carry out the scheme. By the middle of September Dr. Morris had left for Barbados, which had been selected as the headquarters of the new establishment, and tours were at once undertaken to ascertain the requirements of the several islands. The result was the organising of a conference of the authorities on agricultural matters in the West Indian Colonies, each island sending delegates to attend the meetings, which were held, under the presidency of Dr. Morris at Barbados, in January last. On the first anniversary of the day on which the Colonial Secretary publicly set the scheme in motion there arrived in this country the first number of the *West Indian Bulletin*, the journal of the Imperial Agricultural Department for the West Indies, a publication which it is intended to supply gratis to all residents in the islands who ask for it. Its prototype is, naturally, the *Kew Bulletin*, but apparently it will not be issued at regular monthly intervals, only as occasion may require. The first part is a double number of 141 pages, devoted almost wholly to the proceedings at the agricultural conference of January already referred to, the subejcts dealt with being primarily of interest to the Colonists. In addition to the presidential address, dealing generally with the objects of the new Department, there were papers by Prof. d'Albuquerque on "Sugar-cane manurial experiments," and "The teaching of agricultural science at colleges"; by Mr. Bovell on the "Field treatment of the diseases of the sugar-cane," and the "Cost of growing sugar-canes in Barbados"; by Mr. Fawcett on "Agricultural instruction in agricultural schools in Jamaica," "Practical field instruction in Jamaica," and "The prevention of the introduction and spread of fungoid and insect pests in the West Indies"; by Mr. Francis Watts on "Central factories," Mr. William Douglas also dealing with the same subject. The Rev. William Simms discussed "Agricultural education"; Dr. Alford Nicholls, C.M.G., "Suggestions for agricultural development in the Leeward Islands"; Mr. Hart, "Improvement in agricultural methods in the West Indies"; and Prof. Carmody made "Brief suggestions on Colonial industries." The bare recital of the titles of the papers will show what a wide field of investigation and action was opened out, and it behoves all who are interested in the future welfare of

these unfortunate Colonies to secure this first number of the *West Indian Bulletin*, carefully study the array of facts contained therein, and see whether it is not possible to do more for reviving the ancient glories of the islands by personal energy, and the adaptation of modern methods of culture and preparation for the markets of the world, than by any possible benefits that can accrue from abolishing the sugar bounties by France and other countries, or the imposition by us of countervailing duties in favour of our own Colonies. While it is extremely doubtful whether the removal of the bounties would benefit the West Indian sugar planters to any appreciable extent, it seems almost absolutely certain that if they resolutely determined on keeping abreast of the times in management, machinery, selection of plants, &c., instead of being content with what was thought good enough by their fathers and grandfathers before beet-sugar entered into the competition, they would soon see an end to the worst features of that perpetual millstone—the depression in the West Indian sugar industry. As Dr. Morris said in his opening address, "The sugar industry in the smaller islands will never be in a satisfactory condition so long as the processes of crushing the canes and manufacturing the sugar remain as at present." H.

## *SIR EDWARD FRANKLAND, K.C.B., F.R.S.*

NEWS of the death of Sir Edward Frankland will come as a surprise as well as a shock to all his friends, and will be received by the whole scientific world with feelings of the deepest regret.

The end came on Wednesday, August 9, in Norway, where Sir Edward had been in the habit of spending his summer holidays for many years. Born at Churchtown, near Lancaster, on January 18, 1825, he had entered upon his seventy-fifth year, but his upright, spare and active figure until quite recently gave the impression of a much younger man. It was noticeable, however, that he had aged in appearance perceptibly after the death of Lady Frankland (his second wife), which occurred rather suddenly in the spring of the present year.

Frankland received his early education at the Lancaster Grammar School, and subsequently became one of the first science masters at Queenwood College. From Queenwood he proceeded to Germany, and studied chemistry at Marburg and at Giessen. Returning to England he was appointed in 1851 first professor of chemistry at Owens College, Manchester, and there he remained for about seven years till his removal to London in 1857 to take charge of the chemical department in St. Bartholomew's Hospital Medical School. In 1863 he was appointed Fullerian Professor of Chemistry in the Royal Institution, and in 1865 he succeeded Hofmann at the College of Chemistry. The latter chair, which was soon afterwards transferred to the united School of Science and Royal School of Mines at South Kensington, he held till his retirement in 1885. Frankland was for many years a regular attendant at the meetings of the Chemical Society, and was president in 1871–72. His scientific work was rewarded also by honours from many foreign universities and academies, including the Institute of France, of which he was a corresponding member. For the last five years he held the office of Foreign Secretary of the Royal Society, and in 1894 he received the Copley Medal.

Sir Edward received the honour of knighthood in 1897, on the occasion of Her Majesty's Jubilee; but this, strange to say, was conferred, not in recognition of his very eminent services to chemical science, but in his more ordinary professional capacity as water analyst to the Home Department, having been for more than thirty years responsible for the annual reports to the Local Government Board on the quality of the metropolitan water supply.

Frankland's title to fame rests securely upon his important experimental investigations in pure chemistry accomplished chiefly within the twenty years from 1848 to 1868, and upon the impetus which was given to theoretical chemistry by the promulgation of his views concerning the combining capacity, or valency as it is now called, of the elements, which he derived from the results of his experimental work. In the years following 1840 the views of Liebig and of Dumas as to the nature of the carbon compounds, usually spoken of as organic, attracted the attention of the whole chemical world, and efforts were especially directed to the problem of how to isolate the compound radicals which they were supposed to contain in the form of oxide, hydrate, chloride, bromide, iodide and so forth. The radical of common alcohol was naturally one to receive early attention, and to this subject Frankland devoted his earliest efforts. He was successful in 1848 in isolating a substance to which he and all the chemists of that day gave the name *ethyl*, in the belief that it was really the radical of which common alcohol was the hydrate and common ether the oxide, and which was present as the characteristic basis of all the numerous compound ethers or ethereal salts then known. Though in strictness an error, long since corrected by applying the law of Avogadro, was involved in this assumption, the experimental method employed led to the further discovery of the remarkable series of compounds known as organo-metallic, and to the subsequent recognition of the varying power possessed by the metals and metalloids of uniting with alcohol radicals, with the halogens and with oxygen. The recognition of this diversity of combining capacity, and of the fact that each elementary atom possesses a maximum capacity beyond which its power of chemical union is incapable of extending, supplied the basis of the modern doctrine of valency and of all the consequences which follow from the idea of the orderly linking of atoms, afterwards developed by Kekulé into the theory of structure, upon which the whole system of organic chemistry is at the present day established.

At a later period Frankland pursued investigations in the then new and always difficult department of synthetical chemistry. In this he was associated for a time with Mr. B. F. Duppa.

Among others of his researches must be mentioned his experiments on the influence of pressure upon the luminosity of flame. These resulted in a theory of luminosity which for many years divided the favour of chemists and physicists with the older theory of Davy, according to which the luminosity of hydrocarbon flames, at least, is attributed to the presence in the flame of incandescent solid particles. Frankland's theory pointed to the effect of density in the ignited vaporous constituents of luminous flames.

Reference must also be made to the protracted and laborious study of gas and, especially, water supplies, which occupied so many of the later years of his life. Having been appointed a member of the Royal Commission on the Pollution of Rivers and Domestic Water Supply in 1863, he continued henceforward to give close attention to this important subject, and if his analytical methods and his conclusions were not universally adopted, he remained to the end of his life the most eminent authority on the chemical examination of water.

Sir Edward Frankland left several sons and daughters, among whom his eldest son, Dr. Percy Faraday Frankland, F.R.S., professor in the Mason University College, Birmingham, is distinguished as a scientific chemist.

The funeral will take place at Reigate on August 22.

## THE NATIONAL PHYSICAL LABORATORY.

THE realisation of the scheme for the establishment of a National Physical Laboratory is primarily due to two addresses delivered before the British Association in 1891 and 1895 by Prof. Oliver Lodge and the late Sir Douglas Galton respectively. The fact that Sir Douglas Galton, when president of the Association, did all in his power to support the proposal originally made by Prof. Lodge, led to the matter being laid before the Prime Minister by a strong deputation. A committee, of which Lord Rayleigh was chairman, was then appointed by the Treasury, and after taking evidence, reported in favour of the establishment of a public institution for standardising and verifying instruments, for testing materials, and for the determination of physical constants. They further recommended that the institution should be established by extending the Kew Observatory in the Old Deer Park, Richmond, and that the Royal Society should be invited to control it and to nominate a governing body, on which commercial interests should be represented, the choice of the members of such body not being confined to Fellows of the Society.

These recommendations were approved, and to give effect to them the Government undertook to ask Parliament for 12,000*l.* for buildings and for 4000*l.* a year. A scheme for the management of the new institution has been approved by the Treasury, and the first instalment of the promised grants has been sanctioned by the Legislature. The Kew Observatory Committee are willing that the Institution which they have managed very successfully should be merged in the National Physical Laboratory, which will thus become possessed of an endowment of 458*l.* per annum from the Gassiot Trust, and of an income of about 2700*l.* from fees for standardising. These receipts have, in the past, rather more than covered the expenses of carrying on the work of the Observatory.

The ultimate control of the National Physical Laboratory is placed in the hands of the Royal Society, but the constitution of the bodies which manage it directly can only be altered with the consent of the Treasury. These are an Executive Committee and a General Board. The latter is a relatively large body, to which the Executive Committee must report annually, and to which it must submit its scheme of work for the next year. An essential feature in the constitution of the General Board is that twelve of its members are nominated by six of the great technical societies—viz. the Institutions of Civil, Mechanical, Electrical and Naval Engineers, the Iron and Steel Institute, and the Society of Chemical Industry. Six of these representatives of "commercial interests" are also to be members of the Executive Committee, which will ultimately consist of twelve ordinary and five official members, of whom the latter are: the President of the Royal Society, the Chairman of the Committee, the Permanent Secretary of the Board of Trade, and the Treasurer and one of the Secretaries of the Royal Society. In the first instance, six members of the existing Kew Observatory Committee will also have seats on the Executive Committee, but their places will not be filled up when their period of office expires. Finally, it is in the power of the Executive Committee to appoint sub-committees to superintend particular departments or investigations. The members of these sub-committees need not necessarily be members either of the General Board or of the Executive Committee.

Preliminary arrangements have been in progress for some time in order that the National Physical Laboratory should be organised as soon as possible after the requisite funds were voted by Parliament.

The six technical societies have nominated their representatives, the General Board and Executive Committee have been constituted, and general satisfaction will be felt at the announcement that Lord Rayleigh has accepted the chairmanship of these bodies.

On the recommendation of the Executive Committee, the Council of the Royal Society has appointed Mr. R. T. Glazebrook, F.R.S., now Principal of University College, Liverpool, to the important post of Director of the National Physical Laboratory. A number of sub-committees have also been organised by the Executive Committee, which have been requested to make suggestions preparatory to the drawing up of a detailed scheme of work and of the plans of the new buildings.

The members of the Executive Committee are:—

Lord Lister, P.R.S., Lord Rayleigh (*Chairman*), Mr. A. B. Kempe, Treas. R.S., Prof. A. W. Rücker, Sec. R.S., and Sir Courtenay Boyle (*ex officio*), Captain W. de W. Abney, Sir N. Barnaby, Mr. G. Beilby, Sir E. H. Carbutt, Bart., Captain E. W. Creak, R.N., Prof. R. B. Clifton, Prof. G. C. Foster, Mr. F. Galton, Prof. O. J. Lodge, Sir A. Noble, Prof J. Perry, Sir W. Roberts-Austen, Prof. A. Schuster, Mr. A. Siemens, General Sir R. Strachey, Prof. J. J. Thomson, Dr. T. E. Thorpe, Sir J. Wolfe Barry.

In addition to the above, the following are also members of the General Board:—

Sir M. Foster, Sec. R.S. (*ex officio*), Sir F. A. Abel, Bart., Prof. W. G. Adams, Prof. W. E. Ayrton, Mr. H. Bell, Mr. A. Buchan, Mr. R. E. Crompton, Prof. G. F. Fitzgerald, Prof. J. Joly, Lord Kelvin, Mr. J. T. Milton, Sir W. H Preece, Mr. W. F. Reid, the Earl of Rosse, Dr. R. H. Scott, Mr. W. N. Shaw, Mr. C. E. Stromeyer, Admiral Sir W. Wharton, Sir W. H. White.

The following have also been requested to serve on one or other of the sub-committees above referred to:—

Messrs. E. D. Archibald, C. V. Boys, Prof. H. L. Callendar, Messrs. Forbes Carpenter, W. H. M. Christie, J. H. Dallmeyer, Prof. J. A. Ewing, Mr. S. Z. de Ferrant Prof. J. A. Fleming, Messrs. R. E. Froude, E. H. Griffiths, J. Mansergh, T. Matthews, W. H. Maw, Dr. L. Mond, Hon. C. A. Parsons, Prof. A. W. Reinold, Captain H. R. Sankey, Messrs. J. Swinburne, G. J. Symons, H. A. Taylor, Prof. S. P. Thompson, Messrs. J. I. Thornycroft, C. H. Wordingham and A. F. Yarrow.

It will thus be seen that the National Physical Laboratory is being founded on a wide basis. A definite scheme of work will be arranged during the autumn. The Director will, it is hoped, take up the duties of his office on January 1, 1900, and the planning and erection of the new buildings will then proceed with as little delay as possible.

## NOTES.

WE regret to learn that Prof. Bunsen, the veteran chemist, is lying seriously ill at his residence in Heidelberg, and that little hope is entertained of his recovery.

M. DE FONVIELLE, writing from Paris, says: "M. Janssen has left Paris for his usual annual journey to the Observatory on the summit of Mont Blanc, to inspect the instruments installed there.—The Minister of Finance granted to MM. Hermite, at Besançon, the sum of fifty pounds for their experiments with free balloons. It is intended to send up a balloon with new recording apparatus during the forthcoming meeting of the French Association at Boulogne."

MR. BALFOUR has consented to take the chair at a festival dinner at the end of November in aid of the fund now being raised to provide new laboratories at King's College, London.

THE autumn meeting of the Iron and Steel Institute was opened at Manchester on Tuesday, under the presidency of Sir William Roberts-Austen, K.C.B., F.R.S.

THE Superintendent of the U.S. Coast and Geodetic Survey has designated Dr. Frank Schlesinger, Columbia University, New York City, to take charge of the variation of latitude observations at Ukiah, California, in accordance with the plans of the International Geodetic Association.

IT is with great regret that we learn of the death of Dr. Daniel G. Brinton, the distinguished and erudite American anthropologist, in his sixty-third year. Although Dr. Brinton was for many years Professor of American Archæology and Linguistics in the University of Pennsylvania, we understand that he had very little actual teaching to do, and thus was at liberty to devote himself to research. Dr. Brinton was known as an enthusiastic student of linguistics, and had a profound knowledge of American languages. He had recently bequeathed his extensive and very valuable linguistic library to his University The following are some of his contributions to anthropological science: "The Floridean Peninsula: its Indian Tribes and Antiquities"; "The Myths of the New World" (third edition, 1896); "The Religious Sentiment: a Contribution to the Science of Religion"; "American Hero Myths"; "The Chronicles of the Mayas"; "The Annals of the Cakchiquels"; "Ancient Nahuatl Poetry"; "Races and Peoples"; "Lectures on Ethnography"; "Essays of an Americanist"; "The American Race"; "The Pursuit of Happiness"; "Nagualism"; "Grammar of the Choctaw Language"; "Grammar of the Cakchiquel Language," and various other papers and memoirs.

A HURRICANE of unusual severity struck the island of Montserrat, West Indies, on the 7th inst., and caused great devastation there and at other points of its path. It is reported to have reached Porto Rico on the 8th, to have been central over the north-east of Cuba on the 10th, and to have reached the southern part of Florida on the 12th. As pointed out in our note of July 20 last (p. 281), West India hurricanes are most prevalent at this season of the year; the average number between August and November is two a month, but the tracks are often over the open sea, and do not come in contact with the numerous islands. The course taken by the storm in question was more to the northward of the hurricane which caused so much damage at Barbados and St. Vincent last September, and has taken a somewhat more westerly route than the average path. The rate at which it travelled seems to have been under ten miles an hour, which is about the usual velocity in those latitudes; but this has no relation to the force of wind in the whirl of the storm, which probably reached a rate of 100 miles an hour at times. By a telegram from New York on the 12th, the fury of the storm appeared to have abated, probably owing to contact with the land; but for further particulars as to its behaviour, we must wait for the official reports of the Governors of the various islands and of the United States authorities.

PROF. E. VAN AUBEL, assistant professor of physics in the University of Ghent, sends us an interesting note with reference to Dr. C. G. Knott's recent experiments on magnetic strain in bismuth (p. 192) and Mr. Shelford Bidwell's comment upon them (p. 222). It appears that, in 1892, Prof. van Aubel prepared a paper on the same subject, entitled "Influence de l'aimantation sur la longueur d'un barreau de bismuth," and it was published in the *Journal de physique théorique et appliquée* (troisième serie, tome i. p. 424, 1892). His experiments were made with perfectly pure bismuth, prepared by electrolysis, and used by Prof. A. Classen for the determination of the atomic weight of the metal. An interference method was employed to determine any change of length, but no change was found. Prof. van Aubel expresses his satisfaction that the results of his investigation have now been confirmed by Mr. Shelford Bidwell's new experiments.

THE value of towing experiments upon small-scale models of ships for the purpose of deducing the resistance of a full-sized ship from that of the model was first demonstrated by the late Mr. William Froude, whose son, Mr. R. E. Froude, F.R.S., is the superintendent of experiments of this kind at the Admiralty Experimental Works, Gosport. The Construction Bureau of the United States Navy Department has appreciated for many years the value of an experimental basin, but it was unable to secure a grant for the purpose until about two years ago, when Congress granted 100,000 dols. for this work. The basin proper was finished towards the close of last year, and the special machinery and apparatus have now just been completed and installed, after a good deal of delay, due indirectly to the war with Spain. The basin is situated in the Washington Navy Yard, but the building is 500 feet long and about 50 feet wide inside. The water surface of the basin is slightly shorter than the building, being about 470 feet long. The deep portion is about 370 feet long, the south end, from which runs begin, being shallow. The water surface is 43 feet wide, and the depth from top of coping to the bottom of the basin is 14 feet 8 inches. The basin is thus larger than any other in existence, and it is well equipped with machinery for the performance of experiments. Electricity is used to drive the overhead carriage which tows the models; in fact, it is used for all mechanical work in connection with the model tank. Experiments are now being made to determine frictional coefficients of varnished surfaces and other constants needed in the use of the basin. Experiments are also being made as opportunity serves upon models of the naval vessels already built and tried for the purpose of accumulating data which will be constantly needed during the life of the tank.

AN important paper has been recently communicated to the Swedish Academy of Sciences by Dr. Hildebrandsson, Director of Upsala Observatory, entitled "Researches on the centres of action of the atmosphere: II. Rainfall." In a previous paper, published in 1897, it was shown that an intimate relation exists between the variations of barometric pressure in different regions of the earth, *e.g.* if the pressure of the air is above or below the mean at the Azores, the reverse condition would obtain between Iceland and Scotland; and similarly for other parts of the world. Rainfall is perhaps the most important element in the economy of nations, but it is apparently the most variable and irregular of all when dealt with for short periods, but for seasons, or longer periods, considerable regularity is observed. The paper contains tables and curves showing seasonal and yearly values of rainfall for a number of places; and from these it is seen, for instance, that as regards Iceland and the Azores the variations in the rainfall during the cold season are almost always in the opposite direction, and equally clear results are shown to exist for other localities. It is evident that a prediction of rainfall six months in advance would be of great utility in India. With regard to those regions, the author finds that the amount of rainfall between October and March in Siberia is generally in inverse proportion to the amount which will fall in India during the following rainy season. It is not pretended that any definite laws have been determined, but the provisional results seem to be of sufficient importance to warrant a more detailed inquiry.

MR. W. E. HOYLE, Director of the Manchester Museum, Owens College, has presented a very satisfactory report upon the progress made during 1898. The museum is not merely a popular resort, but also an institution which works in many

ways for the advancement of science. The most important gift to the museum during last year was a collection of birds which formed the basis of Mr. H. E. Dresser's work on "The Birds of Europe," and his monographs of the Rollers and of the Bee-eaters. Neither trouble nor expense was spared to make the collection as complete as possible, and more particularly to make it a working collection. As regards the extent of the collection, there are of Bee-eaters about 30 species and 155 specimens, and of Rollers 26 species with 112 specimens; whilst the Western Palæarctic collection contains 721 and the Eastern 260, making a total of 1037 species, or more, according to the British Museum Catalogue. In almost every instance these forms are represented not merely by a single skin but by several, showing the differences of plumage due to sex, age, and local variation, the collection amounting in total to some 10,000 specimens. There are several types and numerous rarities, among which may be mentioned two specimens of the Rosy Gull, whose nesting-place was discovered by Nansen in Franz Josef Land, and two Labrador Falcons. Mr. Hoyle rightly points out that the acquisition of this valuable collection is a piece of singular good fortune for the Manchester Museum, and therefore for all students of ornithology in the neighbourhood.

Some interesting experiments on the corrosion of metals by sea water have (says *Engineering*) been carried out at Kiel during the past two years. The plan followed was to cut off twelve specimens of the metal to be tested, of which three were kept as "witnesses," whilst the other nine were placed in salt water. At the end of eight months three of the latter were withdrawn and compared with the "witnesses." Eight months later a second set were withdrawn and a fresh comparison made, those then left being taken out after the lapse of a third period of eight months. The metals tested included alloys of copper rich in zinc, bronzes containing little zinc, bronzes containing no zinc, pure aluminium bronzes, and finally bronzes containing aluminium and zinc or zinc and iron. The latter in particular showed remarkable resistance to the corrosive powers of sea water, being practically untouched at the end of a two years' immersion. The alloys containing zinc, however, gave much less favourable results. The copper-tin alloys and copper-aluminium alloys and the iron bronzes resisted perfectly when immersed in sea water in contact with iron. The bronzes containing iron, when placed in contact with those of tin, showed a loss by corrosion. It is thus important, if corrosion is to be prevented, to avoid placing these alloys in contact with metals electro-positive to them.

An account of the application of liquefied carbonic acid gas to extinguish underground fires was given by Mr. George Spencer at the recent meeting of the Institution of Mining Engineers. At a colliery with which Mr. Spencer was connected a fire occurred in a heading, as the result of a fall of roof and sides on steam-pipes. The heading was built off with as little delay as possible, but notwithstanding all efforts to shut out the air, sufficient reached the seat of fire to keep it burning slowly. It was therefore decided to apply carbon dioxide, and for this purpose six cylinders of liquefied gas were successfully used. It is not claimed that the method described can be successfully applied to all gob-fires, but there are undoubtedly many cases which might be so treated. In case of fire on shipboard the use of carbon dioxide would no doubt prove invaluable, as it could be quickly applied, and would not cause the same damage to cargoes as water.

The numbers of the *Kew Bulletin* just issued (Nos. 144–146) contain several articles and items of information which serve to show the influence which Kew exerts on botanical science and plant industries in many parts of the world. The life-history of a parasitic fungus which for the past two years has destroyed a considerable number of examples of the beautiful flowering shrub *Prunus japonica*, Thumb., growing in Kew Gardens, is described by Mr. G. Massee, and preventive measures of dealing with it are given. An account is given of experiments made in Queensland for the improvement of the sugar-cane by chemical selection upon a method proposed by Sir William Thiselton-Dyer. The object of the experiments was to ascertain the possibility of increasing the average richness and purity of the juice of a given variety of sugar-cane, by chemical analysis of the juice from each of the "seed canes"—that is, canes from which the plants were to be taken—and by the selection of those plants from the seed canes which were found by the analysis to yield the richest and purest juice. The results of the experiments show clearly that canes planted from rich seed canes selected in this way yielded a juice of higher sucrose content and lower glucose content than canes planted from those shown chemically to be of a "low" grade.

Three new analyses of moldavite glass are published by Dr. C. v. John in the *Verhandlungen der k.k. geolog. Reichsanstalt*, Nos. 6 and 7, 1899. The specimens were handed over by Dr. F. E. Suess for investigation, and with them a specimen of glass from Netin in Moravia, received from Prof. Dvorský, of Brünn. This glass fragment, considered by Drs. Dvorský and Suess to be of artificial origin, was analysed in order that its chemical composition might be compared with that of true moldavite. Similar fragments of artificial glass have been frequently mistaken for moldavite, but differ from the latter in the absence of the characteristic surface sculpture, as also by the different shade of colour. The three specimens of moldavite showed a strikingly similar chemical composition, in which the potash was considerably in excess of the soda. The glass fragment from Netin showed a very different composition, and proved to be a potash glass in which the percentage of potash was abnormally high. The percentage of silica, potash, and soda in moldavite from Budweis was 82·62, 2·28, and 0·63 respectively, while the artificial glass yielded silica 52·32, potash 22·84, and soda 0·24 per cent. The author appends a table containing all the analyses of moldavite known to him, and draws attention to the similarity of composition shown. He remarks that the iron occurs for the most part as ferrous oxide, and that ferric iron is found in larger quantities only in those varieties having a strong brown colour. The belief is expressed that in moldavite the potash is always in excess of the soda, and the author states that in all cases the sum of the alkalis contained is found to be very similar.

In the same number of the *Verhandlungen* is published a paper by A. Rosiwal, in which some additional results of his technical investigation of building-stones are described. In this paper the author clearly explains his new method whereby the relative "freshness" and "degree of weathering" of various building-stones may be expressed in figures. This ingenious method consists in the application of simple formulæ, and it is clearly illustrated by numerous examples.

Dr. Davison's report on the Hereford earthquake of 1896 contains a brief note, by Mr. E. Greenly, on the relation between the intensity of the shock and the geological structure of the Bangor-Anglesey district. In a paper recently published in the *Transactions* of the Edinburgh Geological Society, Mr. Greenly gives the evidence at greater length. He shows that the shock was felt most powerfully in houses standing upon Carboniferous and Ordovician rocks, less so in those upon the hard volcanic series of Bangor, and least of all in the Schistose Complex of Anglesey; the general result being that "the shock

was felt inversely to the degree of elasticity of the rocks." It was, moreover, stronger in the neighbourhood of large boundary faults, where effects due to reflexion would tend to be well-marked. Mr. Greenly also makes the interesting suggestion that, in their passage to the Bangor-Anglesey district, the earth-waves must be influenced by their having to traverse the older palæozoic rocks of the Snowdonian synclinal fold.

DESPITE the important influence of modern theories of oscillatory discharges on our knowledge of the phenomena of lightning, but few attempts seem to have been made to present in a readable and concise form recently observed facts, both theoretical and experimental, bearing on the important question of lightning protection. The Weather Bureau of the United States Department of Agriculture has done good service in publishing, in the form of an illustrated pamphlet of seventy-four pages, a bulletin on "Lightning and the Electricity of the Air," prepared under the direction of Mr. Willis L. Moore. The first part, by Mr. Alexander G. McAdie, is occupied chiefly with theoretical considerations, and includes descriptions of various forms of kites used for modern repetitions of Franklin's experiment, investigations of the potential of the air made on the Washington Monument and elsewhere, notes on auroral displays, photographs of lightning flashes, and a full summary of the best forms of lightning conductors, of general directions for the erection of rods, of precautions to be observed in thunderstorms, and of the treatment of patients struck by lightning. A brief account of the principles of lightning arresters and the use of choke coils for alternating current-circuits concludes this part.

PART II. of the bulletin referred to above, by Mr. Alfred J. Henry, deals with statistics of loss of life and property by lightning, both in the United States and in Europe. It calls attention to the danger to live stock caused by wire fences, the effects of the soil, the kind of trees usually struck (under which head the susceptibility of oaks is prominently shown) and the question as to whether the danger of lightning stroke is increasing or decreasing. In the last question a distinction is made between "cold" strokes and those which cause fire, and it would appear that in Bavaria the total number of strokes is on the increase, but the percentage of fire-causing strokes is on the decrease. This section is illustrated by photographs showing the effects of lightning on different trees, and a map showing the relative frequency of thunderstorms in different parts of the United States.

WE have recently received from Messrs. Williams and Norgate the annual number of *Mittheilungen der Naturforschenden Gesellschaft in Bern* for 1897. In it M. L. Crelier contributes a paper on the Bessel's function of the second kind $S_n(x)$, in which are deduced a number of formulæ involving Bessel's functions, which the author claims to be new. An account of the exhumation of the late Jacob Steiner is also given, accompanied by measurements of the great mathematician's skull.

PROF. AUGUSTO RIGHI contributes to the *Rendiconti* of the Bologna Academy a paper on the absorption of light on the part of a gas placed in a magnetic field. This forms a continuation of Prof. Righi's investigations on the Zeeman effect. The new experiments, conducted with the aid of a large Rowland's grating, deal chiefly with the inverse of Zeeman's phenomena, both with hypoazotid and with polarised light in sodium vapour. The investigation has an important bearing on results previously obtained by Macaluso and Corbino.

M. E. H. AMAGAT, writing in the *Journal de Physique* for July, proposes a new form of the relation $f(p, v, \mathrm{T})=0$ for fluids. From considerations, partly theoretical and partly experimental, M. Amagat is led to adopt the formula

$$\left\{p+\frac{v-[a+m(v-b)+c/(v-b)]\mathrm{T}}{kvr-\alpha+n\sqrt{[(v-\beta)^2+d^2]}}\right\}v=\mathrm{RT},$$

a formula which, in the case of carbonic acid, agrees closely with observations of the pressures corresponding to given volumes and temperatures, both in the gaseous state and along the curve of saturation.

A NEW classification of the Tineæ of Central Europe is given by Dr. Arnold Spuler in the *Sitzungsberichte der physikalisch-medicinischen Societät* (Erlangen) for 1898. Dr. Spuler follows modern views in placing the large Cossidæ among the Tineæ next before the family Tortricoidæ.

WE have just received two new parts of the *Bulletin* of the New York State Museum (vol. vi. Nos. 26 and 27, April and May 1899). Both are by Dr. Ephraim Porter Felt, State Entomologist. The first relates to the collection, preservation, and distribution of New York insects, and contains illustrations of apparatus. The second concerns shade-tree pests, and relates to various Coleoptera, Lepidoptera, Hymenoptera, and Hemiptera. It is illustrated, though it is but a small pamphlet, with five admirable plates, besides figures in the text.

THE volume containing the numbers of the *Bulletin of Miscellaneous Information* issued by the Royal Gardens, Kew, during 1898, has just been published. Many of the articles in this most serviceable publication have already been referred to in these columns, and we need now only call attention to the issue of them in a form convenient for reference. Particular attention is given in the volume to the cultivation of rubber plants, artificial indigo, China grass, and other subjects of economic importance.

THE seventh Robert Boyle Lecture on the "Physiological Perception of Musical Tone," delivered before the Oxford University Scientific Club on June 6, by Prof. J. G. McKendrick F.R.S., has been published in pamphlet form by Mr. Henry Frowde. An abstract of the lecture appeared in NATURE of June 15.

THE publication of a series of "Studien und Skizzen aus Naturwissenschaft und Philosophie," by Dr. Adolf Wagner, has been commenced by the firm of the Gebrüder Borntraeger, Berlin. The first volume is an essay "Über wissenschaftliches Denken und über populäre Wissenschaft," which should be read by persons who instruct the scientific laity by spoken or written words; and the second volume is concerned with the "Problem der Willensfreiheit." A number of other volumes are in preparation.

A DESCRIPTIVE catalogue of the Tunicata in the Australian Museum, Sydney, N.S.W., prepared by Prof. W. A. Herdman, F.R.S., has been published by order of the Trustees of the Museum. The collection upon which the catalogue is based was sent to Prof. Herdman several years ago, but certain circumstances prevented the publication of the work in 1893, when it was ready for press. The work is not put forward as a monograph on Australian Tunicata, so the only anatomical and histological details included are those required for the description of the various species. A list of the Tunicata Fauna of Australian seas, so far as it is at present known, is given, and also a brief general account of the structure and life-history of a typical Ascidian, which may be of service to students referring to the catalogue. Numerous plates illustrate the various species described.

THE additions to the Zoological Society's Gardens during the past week include a Pinche Monkey (*Midas aedipus*) from

Colombia, presented by Mr. R. E. Stone; two Common Duikers (*Cephalophus grimmi*), six Swainson's Francolins (*Pternistes swainsoni*) from South Africa, presented by Mr. J. E. Matcham; a Suricate (*Suricata tetradactyla*) from South Africa, a Common Hamster (Albino) (*Cricetus frumentarius*), European; an Antillean Boa (*Boa diviniloque*) from the West Indies, deposited; two Spotted Turtle Doves (*Turtur suratensis*), bred in the Gardens.

MOTION OF APSE LINE OF $\alpha$ GEMINORUM.—In a previous communication to the *Mem. Soc. Degli Spett. Ital.* (vol. xxvi., 1897), M. A. Belopolsky has drawn attention to the rapid motion of the line of apsides in the system of $\alpha$ Geminorum (Castor), and now, in the last issue of the same journal (vol. xxviii. pp. 103–108, 1899), he gives the results of more recent work on this interesting double star. The former measures were obtained from a series of spectrographs obtained at Pulkowa during one year, and were not sufficiently representative to give certain results. He has now at his disposal observations which he has made during the past three years, and in the present paper confines himself to the examination of three groups of these observations, reserving the discussion of the whole for a later article. These groups of observations embrace the periods: (1) 1896, March 8 to April 26; (2) 1898, March 15 to May 2; (3) 1899, January 19 to April 16. In the calculation several difficulties are found, the chief of which are the rapid movement (period 2·93 days), the uncertainty of a few thousandths of the period producing an error of several degrees in the true anomaly, and also the uncertainty of the time of passage through *Periastron*.

Tables are given showing comparisons between the calculated and observed values for the velocity in the line of sight, for all the dates in the three groups of observations, from which the author concludes that the probable error is only about ± 0·368 l.g. (± 0·92 miles). He finally concludes that the observed rapid movement of the line of apsides is real, and that the *period of this revolution* is

4 years 40 days = 2100 days.

He attributes the cause of this to the probable flattening of the components, and mentions that a flattening of one-seventh would be sufficient, if the dimensions of the system are equal to those of Algol, to produce the observed motion.

MR. TEBBUTT'S OBSERVATORY.—In presenting his report of the work done at his observatory at Windsor, New South Wales, during the year 1898, Mr. John Tebbutt states that the past year was remarkable for the large number of clear nights during the autumn, winter and spring months, rendering it possible to get a large amount of work done.

Meridian work was carried out with a 3-inch Cooke transit, the timekeeper being a Poole 8-day chronometer.

Extra-meridian work consisted of observations of occultations, planets, and comets. With the 8-inch equatorial thirty-six disappearances at the moon's dark limb were measured and the results published. The same instrument, in conjunction with the Grubb filar micrometer, was employed on fifty-seven nights in planetary observation; 73 comparisons of Vesta, 211 of Iris, 107 of Isis, 91 of Jupiter and $\eta$ Virginis, 132 of Uranus and $\omega^1$ Scorpii, and 132 of Uranus and $\omega^2$ Scorpii, were recorded; and comparisons with the measures published by other observers have proved to be very satisfactory.

The observations of comets have been made with both the 4½-inch and 8-inch equatorials, and have included measures of Encke's Comet, and Comet Coddington-Pauly, the latter being followed from June 15 to March 3, 764 measures of the comet and 138 of comparison stars being made on 103 nights during that period.

Attempts to observe Comets Perrine, *e* and *h*, 1898, were unsuccessful owing to their proximity to the sun.

All the observations, computations and reductions have been made by the proprietor of the observatory, it being extremely difficult to obtain even occasional assistance.

TEMPERATURES IN GASEOUS NEBULÆ.—Mr. F. E. Nipher, in a paper read before the Academy of Science, St Louis (vol. ix., No. 4), discussed the conditions of temperature, &c., in a gravitating nebula having *uniform temperature* throughout its mass. In a second paper he now discusses the same subject on the different assumption that the initial temperature *diminishes* from the centre outwards. After a lengthy mathematical discussion he derives a general formula

$$T = T_0(1+n)\left(\frac{r_0}{r}\right)^{1-n}$$

which reduces to Ritter's equation if the temperature of the mass be assumed initially uniform. He concludes that in general the temperature throughout a nebula is to be given in terms of the coordinates of the point in space where the temperature is to be determined, and the *ratio of contraction* from any given initial condition. If the temperature remains constant throughout the mass, then Ritter's equation would hold during contraction. If on account of unequal permeability to heat the temperature should become unequal, the law of temperature change as a function of the ratio of contraction becomes more complex, so that if at any time the temperature varies inversely as the *n*th power of the distance from the centre, the ratio of temperature change at any contracting surface will be given by the above equation, in which it is evident, from physical conditions, that $n$ cannot be less than zero.

## THE RECENT PERSEID METEORIC SHOWER.

A SERIES of very clear nights enabled the Perseids to be well observed this year. The shower was not of unusual brilliancy, but it furnished a considerable number of meteors, and they appear to have been widely observed. The occurrence of the Perseid display now excites not only the attention of the meteoric enthusiast, but is seriously observed by astronomers generally, and the application of photography to work of this kind has greatly stimulated the interest in it.

On August 9 the writer watched the north-eastern sky between about 10h. 15m. and 13h., but a few clouds prevailed during the first hour. 38 meteors were seen, of which 26 were Perseids. On August 10, between about 10h. and 13h. 30m., 91 meteors were seen, of which 72 were Perseids. On August 11, between 10h. and 13h. 30m., 90 meteors were observed, including 68 Perseids. On August 12, between 10h. and 13h. 30m., 62 meteors were counted, and amongst these were 43 Perseids. On August 13, 23 meteors (10 Perseids) were seen in 2 hours, and on August 14, 29 meteors (12 Perseids) were recorded in 2¼ hours.

On August 10, between 11h. 10m. and 14h. 35m., Prof. A. S. Herschel at Slough observed 104 meteors, and after making allowance for time spent in registering the paths the horary number of meteors for one observer would be about 40. He describes the maximum as having been observed between 12h. and 12h. 30m., when several bright meteors succeeded each other at short intervals.

On August 10 Mr. T. H. Astbury, observing at Shifnal, Salop, says that thirty-four meteors were seen between 10h. and 11h., the great majority being Perseids. There was also an active radiant in Cygnus.

On August 11 only about eighteen meteors were seen from 10h. till 11h., so that he concluded the maximum occurred on the 10th, when the meteors were brighter and more numerous.

According to the Bristol observations already alluded to, very little decline in numbers was, however, noticed on August 11, and to exhibit this more readily, the following table has been compiled:—

| Date. | Time of observation. h. h. | Actual length. hrs. | Meteors seen. | Perseids. | Radiant. α | δ |
|---|---|---|---|---|---|---|
| Aug. 9 | $10\frac{1}{4}$–$12\frac{3}{4}$ | 2 | 38 | 26 | 44° | + 57° |
| 10 | 10 –$13\frac{1}{2}$ | 3 | 91 | 72 | 44 | + 57 |
| 11 | 10 –$13\frac{1}{2}$ | 3 | 90 | 68 | 46 | + 57 |
| 12 | 10 –$13\frac{1}{2}$ | 3 | 62 | 43 | 48 | + 57 |
| 13 | 10 –$12\frac{1}{2}$ | 2 | 23 | 10 | 49 | + 58 |
| 14 | 10 –$12\frac{1}{2}$ | $2\frac{1}{4}$ | 29 | 12 | 50 | + 56 |

The meteors seen on the 10th were, however, rather brighter on the whole than those on the 11th. The largest meteors were as follows:—

| No. | Date. | Time. | Mag. | Path. From | | To | |
|---|---|---|---|---|---|---|---|
| 1 | Aug. 9 | 11 4 | ♃ | 15° | + 28° | 11° | + 21 |
| 2 | | 11 32 | ♃ | $296\frac{1}{2}$ | + 57 | 278 | + $36\frac{1}{2}$ |
| 3 | | 12 7 | ♀ | 239 | + 60 | 235 | + 37 |
| 4 | Aug. 10 | 10 14 | ♀ | 293 | + 60 | 271 | + 38 |
| 5 | | 10 54 | ♃ | $23\frac{1}{2}$ | + 38 | 17 | + 29 |
| 6 | | 11 36 | ♃ | $49\frac{1}{2}$ | + $37\frac{1}{2}$ | $50\frac{1}{2}$ | + 32 |
| 7 | | 13 18 | ♃ | 50 | + 67 | 58 | + 73 |
| 8 | Aug. 11 | 11 9 | ♃ | $18\frac{1}{2}$ | + 51 | 5 | + $44\frac{1}{2}$ |
| 9 | Aug. 12 | 10 16 | ♃ | $5\frac{1}{2}$ | + 6 | 1 | − 6 |
| 10 | | 10 39 | ♃ | 326 | + $1\frac{1}{2}$ | 318 | − 11 |
| 11 | | 12 $1\frac{1}{2}$ | ♀ | $4\frac{1}{2}$ | + 43 | 347 | + $27\frac{1}{2}$ |

No. 3 was also seen by Prof. Herschel, and No. 4 by Mr. Astbury. The majority of the remainder were seen by various other observers, and their real paths will be calculated.

On August 12 the shower had markedly declined, though it was tolerably active between 10h. and 11h. The position of the radiant point exhibited the usual diurnal motion to the eastward. On July 29–August 2, eight meteors observed at Bristol denoted the radiant at 34° + 54°, and on August 6, six meteors fixed it at 40° + 55°. On August 12 it was in 48° + 57° and on August 14 in 50° + 56°.

Several remarkable meteors with very slow motion, and leaving trains of sparks, were recorded on August 12. One of the most striking of these appeared at 12h. 31m. It was of the 1st mag., and traversed a path of 33 degrees from 341° + 81° to 124° + 64° in about seven seconds. As it fell almost perpendicularly down the northern sky the nucleus poured out a stream of yellow sparks. Probably the radiant was near the southern horizon, and it is hoped that other observers will send in reports of this curious meteor, and enable its true radiant to be found.

Altogether the display seems to have been of average importance, and to have fallen below the observed strength of the shower on August 11, 1898. Many of the minor showers of the period made themselves apparent, though they were generally very feeble. The principal of them were at 41° + 20°, 333° + 26°, 345 ± 0, 315° + 77°, 339° 11° and 17° + 31°. It is to be hoped that at places where the photographic method has been applied the results have been successful.

W. F. DENNING.

## *UNITED STATES DEEP-SEA EXPLORING EXPEDITION.*

THE announcement that the U.S. Fish Commission steamer, *Albatross*, would shortly be despatched on an exploring expedition to the Pacific Ocean, has already been noticed in these columns. Particulars of the main objects of the expedition, and the route to be followed, are given by Mr. H. M. Smith in the *National Geographic Magazine*, from which the subjoined account has been abridged.

The *Albatross* is the best-equipped vessel afloat for deep-sea investigation, for which work she was especially constructed for the Fish Commission in 1882, at a cost of nearly 200,000 dollars. She is a twin-screw steamer of 384 tons burden, 234 feet long and $27\frac{1}{2}$ feet beam. A full account of the construction of the *Albatross* and her appliances for marine investigation has been given in the admirable work on "Deep-sea Exploration," by Commander Z. L. Tanner, U.S.N., under whose direction the vessel was built and who was in command from the date of her launching until 1894. The reputation long enjoyed by the *Albatross* of being unequalled in effectiveness for marine research will be more than ever deserved on the approaching cruise because of the extensive improvements and repairs she has recently undergone, including the installation of new boilers, ice-making machine, cold-storage plant, &c., together with the thorough replenishing of the scientific outfit.

The *Albatross* will pass through the Golden Gate on August 21 and begin her long voyage to certain groups of islands in the middle of the Pacific Ocean, both north and south of the equator, whose local fauna is almost unknown, while in the adjacent waters little or no scientific investigation has been carried on. The Society islands will be first visited, although the vessel will touch at the Marquesas islands for coal. Between San Francisco and Tahiti, a distance of 3500 miles, dredging and sounding will be carried on at regular intervals on a section of the sea-bottom almost wholly unexplored. Tahiti will be the headquarters while the Society islands and the Paumota islands are being explored. In the latter archipelago, which is about 600 miles long, six or eight weeks will be spent and important scientific discoveries should be made. In the Tonga or Friendly islands, distant about 1500 miles from the Society group, a week or ten days will be passed. The vessel will then proceed to the Fiji islands, where a short stay will be made, and thence 1700 miles to the Marshall islands, in which interesting archipelago, of whose natural history almost nothing is known, six or seven weeks will be devoted to exploration. The Ellice and Gilbert islands, lying between the Fiji and Marshall islands, will also be visited. It was originally the intention to have the *Albatross* proceed from the Marshall islands to the Hawaiian islands and thence to San Francisco, running a line of deep-sea dredgings along the entire route; but, owing to the prevalence of head winds at the time when the vessel will be ready to leave the Marshall islands, this plan has been abandoned, and instead the vessel will sail for Japan, making frequent use of the dredge and the deep-sea tow-net and setting the trawl in the moderately deep water off the Japan coast, where the fishermen are continually bringing up curious forms. The voyage of nearly 20,000 miles will come to an end at Yokohama, where the *Albatross* will arrive in April 1900, and refit for a summer cruise to Alaska to resume the systematic examination of the salmon streams begun several years ago.

The leading features of the expedition will be deep-sea dredging, trawling, and sounding, and some special appliances for such work have been constructed. A wire dredge-rope 6000 fathoms long has been made to order, and to accommodate this enormous quantity a special drum has had to be prepared. It is expected that both the dredge and the beam-trawl will be hauled in deeper water than heretofore. One of the novel pieces of collecting apparatus is a beam-trawl of unprecedentedly large size, especially designed for the capture of larger animals than can be taken with the usual apparatus.

While the deep-sea investigations will receive the most attention, surface and intermediate towing, shore-seining, and fishing trials with lines, gill-nets, and other appliances will be regularly carried on and will undoubtedly yield rich collections. The region to be visited abounds in atolls and elevated reefs, many of which will be visited and studied for the purpose of obtaining data bearing on the disputed question of the origin of coral reefs.

The *Albatross* is manned by about ten officers and seventy petty officers and enlisted men of the United States Navy. The commanding officer is Lieutenant Commander Jefferson F. Moser, U.S.N. The civilian staff on this expedition consists of Prof. Alexander Agassiz, in charge of the scientific work, who will be accompanied by his son and his personal assistants; Dr. W. McM. Woodworth and Dr. A. G. Mayer, of the Museum of Comparative Zoology, Cambridge, Mass.; Dr. H. F. Moore, chief naturalist of the *Albatross*; Mr. Charles H. Townsend, formerly naturalist, now chief of the fisheries division of the U.S. Fish Commission; Mr. A. B. Alexander, fishery expert, and Mr. H. G. Fassett, photographer, both of the U.S. Fish Commission.

Opportunity will undoubtedly be afforded for conducting a number of important collateral inquiries without detriment to the regular scientific work. Advantage will be taken of every chance to obtain for the National Museum specimens of the mammals, birds, insects, and other land animals of the various islands visited. A study of the aboriginal fishing methods, apparatus, and boats, and the collection of specimens of the native fishing appliances will be in charge of the fishery expert.

The Smithsonian Institution has specially requested that the Fish Commission make an effort to trace the origin of some of

the ethnological specimens brought back from the Pacific islands by the Wilkes Exploring Expedition. Commissioner Bowers has notified the Smithsonian Institution that the naval and civil attachés of the vessel will be given special instructions to be on the look-out for desirable ethnological material.

There is every reason to believe that this expedition will yield valuable scientific results, and will be creditable to the United States. It is the most important marine expedition on which the Fish Commission has embarked, and one of the most promising scientific enterprises in which the U.S. Government has ever engaged. It is a matter for congratulation that, in the activity in exploration of the seas now being exhibited by various Governments, the United States will participate under such favourable auspices and be represented by a man of science of such wide experience in deep-sea investigation as Prof. Agassiz.

## *MAGNETO-OPTIC ROTATION AND ITS EXPLANATION BY A GYROSTATIC SYSTEM.*[1]

THE action of magnetism on the propagation of light in a transparent medium has been rightly regarded as one of the most beautiful of Faraday's great scientific discoveries. Like most important discoveries it was no result of accidental observation, but was the outcome of long and patient inquiry. Guided by a conviction that (to quote his own words) "the various forms under which the forces of matter are made manifest have one common origin," he made many attempts to discover a relation between light and electricity, but for very long with negative results. Still, however, retaining a strong persuasion that his view was correct, and that some such relation must exist, he was undiscouraged, and only proceeded to search for it more strictly and carefully than ever. At last, as he himself says, he "succeeded in *magnetising and electrifying a ray of light, and in illuminating a magnetic line of force.*"

Faraday pictured the space round a magnet as permeated by what he called lines of force; these he regarded as no mere mathematical abstractions, but as having a real physical existence represented by a change of state of the medium brought about by the introduction of the magnet. That there is such a medium surrounding a magnet we take for granted. The lines of force are shown by the directions which the small elongated pieces of iron we have in iron filings take when sprinkled on a smooth horizontal surface surrounding a horizontal bar magnet, as in the experiment I here make. [*Experiment to show field of bar magnet by iron filings.*]

The arrangement of these lines of force depends upon the nature of the magnet producing them. If the magnet be of horse-shoe shape, the lines are crowded into the space between the poles; and if the pole faces be close together and have their opposed surfaces flat and parallel the lines of force pass straight across from one surface to the other in the manner shown in the diagram before you. [*Diagram of field between flat pole faces.*]

The physical existence of these lines of force was demonstrated for a number of different media by the discovery of Faraday to which I have already referred, and on which almost all the later work on the relation of magnetism to light has been founded. I am permitted by the kindness of the authorities of this Institution to exhibit here the very apparatus which Faraday himself employed, though for the various experiments I have to make it is necessary to actually use another set of instruments. [*Apparatus shown.*] Before repeating Faraday's experiment, let me describe shortly what I propose to do, and the effect to be observed.

A beam of plane polarised light is produced by passing white light from this electric lamp through a Nicol's prism. To understand the nature of plane polarised light, look for a moment at this other diagram (Fig. 1). It represents a series of particles displaced in a certain regular manner to different distances from the mean or equilibrium positions they originally had along a straight line. They are moving in the directions shown by the arrows and with velocities depending on their positions, as indicated by the lengths of the arrows. Suppose a certain interval of time to elapse. The particles will have moved in that time to the positions shown in this other diagram (Fig. 2) on the same sheet. It will be seen that the velocities as well as the positions of the particles have altered; but that the configuration is the same as would be given by the former diagram moved through a certain distance to the left.

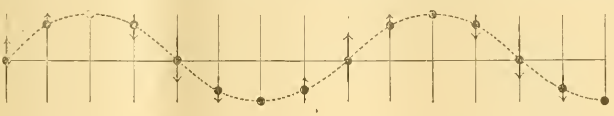

FIG. 1.

Thus an observer looking at the particles and regarding their configuration would see that configuration apparently move to the left; and this, it is very carefully to be noted, is a result of the transverse motions of the individual particles. In another interval of time equal to the former the arrangement of particles will appear to have moved a further distance of the same amount towards the left.

This transverse motion of the particles, thus shown displaced from their equilibrium positions, represents the vibration of the medium which is the vehicle of light, and the right to left motion of the configuration of particles is the wave motion resulting from that vibration. I do not say that the medium is thus made up of discrete particles, or that the different portions of it vibrate in this manner, but there is undoubtedly a directed quantity transverse to the direction in which the wave is travelling, the value of which at different points may be represented by the displacements of the particles, and which varies in the same manner, and results, as here shown, in the propagation of a wave of the quantity concerned.

FIG. 2

In fact, we have here a representation of a wave of plane polarised light. The directions of vibration are right lines parallel at all points along the wave. Ordinary light consists of vibrations the directions of which are not parallel if rectilinear, and each vibration is therefore capable of being resolved into two in directions at right angles to one another. The Nicol's prism, in fact, splits a wave of ordinary unpolarised light into two waves, one in which the vibrations are in one plane containing the direction in which the light is travelling, the other in a plane containing the same direction, but at right angles to the former. One of these waves is stopped by the film of Canada balsam in the prism and thrown out of its course, while the other wave is allowed to pass on undisturbed.

If the wave thus allowed to pass by one Nicol's prism be received by another it is found that there are two positions of the latter in which the wave passes freely through the second

[1] A discourse delivered at the Royal Institution by Prof. Andrew Gray, F.R.S.

prism, and two others in which the wave is stopped. The prism can be turned from one position to another by properly placing it and then turning it round the direction of the ray. It is found that if the prism be thus turned from a position in which the light is freely transmitted we come after turning it through 90° to a position in which the light is stopped, and that if we go on turning through another angle of 90° a position is reached in which the light is again freely transmitted, and so on, the light being alternately stopped and transmitted by the second prisms in successive positions 90° apart.

The mode of passage of the wave by the Nicols when their planes are parallel, and its stoppage when the planes are crossed, are illustrated by this diagram (Fig. 3) of a vibrating cord and two slits. When the slits are parallel, the vibration

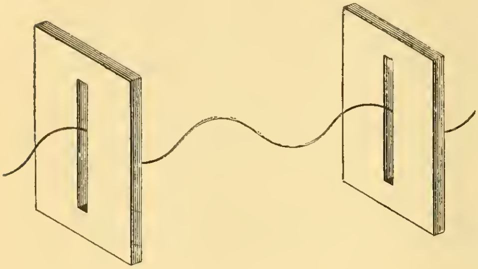

FIG. 3

which is passed by one is passed by the other; when they are crossed, a vibration passed by one is stopped by the other.

Two planes of symmetry of the prisms parallel to the ray, and called their principal planes, are parallel to one another when the light passes through both, and are perpendicular to one another when the light passed by the first is stopped by the second. We shall call the first prism the polarising prism, or the *polariser*, from its effect in producing plane polarised light; the other, the *analyser*. The stoppage of the light in the two positions 180° apart of the second prism and its passage in the two intermediate positions show that the light passed by the first prism is plane polarised.

Now a beam of plane polarised light is passed through the perforated pole-pieces of this large electro-magnet (Fig. 4), so

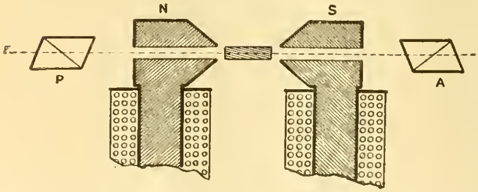

FIG. 4.

that the beam travels between the pole faces along the direction which the lines of force there would have if the magnet were excited by a current. The arrangement of the apparatus is as shown in the diagram. The light is polarised by the prism P, passes through the magnetic field, and then through the analysing prism A, to the screen. As you see, when the second prism is turned round the ray the light on the screen alternately shines out and is extinguished, and you can see also that the angle between the positions of free passage and extinction is 90°.

I now place in the path of the beam this bar of a very remarkable kind of glass, some of the properties of which were investigated by Faraday. It is a very dense kind of lead glass, which may be described as a silicated borate of lead; that is, it contains silica, boric acid and lead oxide. The beam is not disturbed although the light passes through the glass from end to end. I now adjust the analysing prism to very nearly complete extinction, and then excite the magnet. If the room is sufficiently darkened I think all will see that when the magnet is excited there is a very perceptible brightening of the dim patch of light on the screen, and that this brightening disappears when the current is removed from the magnet. This is Faraday's discovery.

How are we to describe this result? What effect has been produced by the magnetic field? It is clear that the direction of vibration of the light emerging from the specimen of heavy glass has been changed relatively to the prism so that the light now readily passes. It is found, moreover, that the amount of turning of the direction of vibration round the ray is proportional to the length of the specimen, so that the directions of vibration at different points along the wave within the specimen lie on a helically twisted surface, and may be regarded as represented by the straight rods in the model before you on the table (Fig. 5).

It is also found that the amount of the turning depends on the intensity of the magnetic field—is, in fact, simply proportional to that intensity. Hence the turning is proportional to the mean intensity of the field, and to the length of the path in the medium, that is, to the products of these two quantities. It also depends on the nature of the medium. The angle of turning produced by a field of known intensity when the ray passes through bisulphide of carbon has been very carefully measured by Lord Rayleigh, whose results are of great value for other magnetic work.

The law of proportionality of the amount of turning of the plane of polarisation to the intensity of the magnetic field in

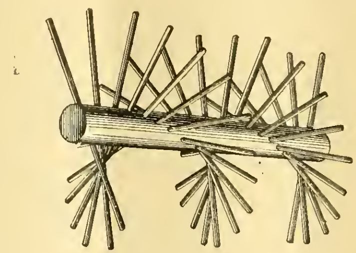

FIG. 5.

the space in which the substance is placed is not, however, to be regarded as established for strongly magnetic substances, such as iron, nickel or cobalt. The matter has not yet been completely worked out, but the turning in such cases seems to be more nearly proportional to the intensity of magnetisation, a different quantity from the intensity of the magnetic field producing the magnetisation. If this law be found correct the angle of turning will be proportional to the product of the intensity of magnetisation and to the length of the path; and the angle observed divided by this product will give another constant, which has been called Kundt's constant.

The rotation of the plane of polarisation in strongly magnetised substances was investigated by Kundt, the very eminent head of the Physical Laboratory of the University of Berlin, who died only a year or two ago. Kundt is remembered for many beautiful methods which he introduced into quantitative physical work; but no work he did was more remarkable than that which he performed in magneto-optic rotation when he succeeded in passing a beam of plane polarised light through plates of iron, nickel and cobalt. Such substances, though apparently opaque to light, are not really so when obtained in plates of sufficient thinness. In sufficiently thin films all metals, so far as I know, are transparent, not merely to Röntgen rays, but to ordinary light. Kundt conceived the idea of forming such films of the strongly magnetic metals, so as to investigate their properties as regards magneto-optic rotation. He succeeded in obtaining them by electroplating platinised glass with such thin

stratums of these metals that light passed through them in sufficient quantity for observation. The rotation produced by the glass and the exceedingly thin film of platinum was determined once for all and allowed for. Kundt obtained the remarkable result that the magnetic rotatory power in iron is so great that light transmitted through a thickness of one centimetre of iron magnetised to saturation is turned through an angle of over 200,000°, that is, that light passing through a thickness of an inch of iron magnetised to saturation would have its plane of polarisation turned completely round more than a thousand times; in other words, one complete turn would be given by a film less than $\frac{1}{1000}$ of an inch in thickness. A scarcely smaller result has been found by Du Bois for cobalt, and a maximum rotation of rather less than half as much by the same experimenter for nickel.

The direction of turning in all the cases which have so far been specified—that is, Faraday's glass, bisulphide of carbon, iron, nickel and cobalt—is the same as that in which a current of electricity would have to flow round the spires of a coil of wire surrounding the specimen so as to produce the magnetic field. This we call the *positive* direction. There are, however, many substances in which the turning produced by the magnetic field is in the contrary or negative direction; for example, ferrous and ferric salts of iron, chromate and bichromate of potassium, and in fact most compound substances which are feebly magnetic.

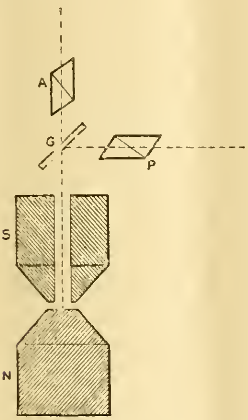

FIG. 6.

Faraday established by his experiments the fact that substances fall into two distinct classes as tested by their behaviour under the influence of magnetic force. For example, an elongated specimen of iron, nickel or cobalt, if freely suspended horizontally between the poles of our electro-magnet, would set itself with its length along the lines of force. On the other hand, a similar specimen of heavy glass, or a tube filled with bisulphide of carbon, would, if similarly suspended, set itself across the lines of force. The former substances were therefore called by Faraday paramagnetic, the latter diamagnetic.

It might be supposed that diamagnetics would show a turning effect opposed to that found in paramagnetics, but this is not the case. As we have seen, bisulphide of carbon and heavy glass, which are diamagnetics, show a turning in the same direction as that produced in iron—as indeed do most solid, fluid and gaseous diamagnetics. Feebly paramagnetic compound substances, on the other hand, produce negative rotation.

A theory of diamagnetism has been put forward in which the phenomena are explained by supposing that all substances are paramagnetic in reality, but that so-called diamagnetic bodies are less so than the air in which they are immersed when experimented on. Thus the diamagnetic quality is one of the substance relatively to air, in the same kind of way as the apparent levity of a balloon is due to the fact that its total weight has a positive value, but is less than that of the air displaced by the balloon and appendages. Lord Kelvin's dynamical explanation of magneto-optic rotation does not bear out this view of the matter.

Before passing to the dynamical explanation, however, I must very shortly call attention to some remarkable discoveries in this subject made by Dr. John Kerr, of Glasgow. I have here an electro-magnet arranged as in the diagram before you (Fig. 6). The light from the lamp is first plane polarised by the Nicol P, then it is thrown on the piece of silvered glass G, and part of it is thereby reflected through this perforated pole-piece so as to fall normally on the polished point of the other pole-piece. Reflection thus takes place at perpendicular incidence, and the reflected light is received by this second Nicol. When the magnet is unexcited the second Nicol is arranged so as to quench the reflected light. The magnet is then excited, and it is found that the light is faintly restored, showing that an effect on the polarisation of the light has been produced by the magnetisation. It is to be noticed here that the incident and reflected light is in the direction of magnetisation. We shall not pause to make this experiment. It was arranged this morning and successfully carried out; but the effect is slight, and might not be noticeable without precautions, which we have hardly time to make, to exclude all extraneous light from the screen.

It would perhaps be incorrect to say that the plane of polarisation has been rotated in this case, as it has been asserted by Righi that the light after reflection is no longer plane polarised, but that there are two components of vibration at right angles to one another, so related that the resultant vibration is not

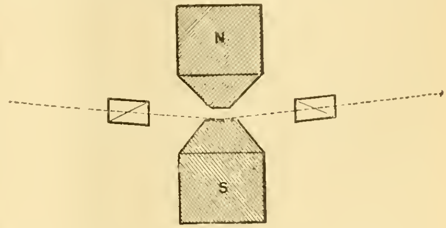

FIG. 7.

rectilinear but elliptical. There is therefore no position in which the analysing prism can be placed so as to extinguish the reflected light. The transverse component necessary to give the elliptic vibration is, however, in this case, if it exists, very small, and very nearly complete extinction of the beam can be obtained by turning the analysing prism round so as to stop the other component vibration. The angle through which the prism must be turned to effect this is the amount of the apparent rotation. The direction of rotation is reversed by reversing the magnetism of the reflecting pole. Dr. Kerr found that the direction is always that in which the current flows in the coils producing the magnetisation of the pole.

Dr. Kerr also made experiments with light obliquely incident on a pole-face, with the arrangement of apparatus shown in this other diagram (Fig. 7). He found that the previously plane polarised light was by the reflection rendered slightly elliptically polarised. A slight turning of the analysing Nicol was necessary to place it so as to stop the vibration corresponding to the long axis of the ellipse and so secure imperfect extinction.

These effects are, like those of normal incidence, very small, and they can hardly be shown to an audience.

(*To be continued.*)

## SCIENCE SCHOOLS AND CLASSES.[1]

THE annual Report of the Department of Science and Art furnishes much information on the progress made in elementary scientific instruction year by year; and the following facts, derived from the Report just published, shows the vast extent of the Department's operations during 1898. The number of students under instruction in schools eligible for the

[1] Forty-sixth Report of the Department of Science and Art of the Committee of Council on Education, with appendices. Pp. 320. (H.M. Stationery Office, 1899.)

Department's grants in that year was 158,370. These students were distributed among 11,723 classes in 2023 different schools. Scotch schools and students are not included in these figures, the Scotch Education Department having taken over the administration of grants for science and art instruction. Even more satisfactory than the increase of the number of pupils receiving science instruction is the fact that in 1898 there were 159 Schools of Science—that is, schools following an organised course of scientific instruction—in which practical work forms an essential part. The number of students in these schools was 21,193. This is a considerable increase on the preceding year, when the number of Schools of Science was 143, with 18,142 students.

For the year 1898 the grants to science schools in England, Wales and Ireland, exclusive of those made to training colleges, amounted to 169,604*l.* 3*s.* 3*d.* The sum included (*a*) 85,862*l.* to science schools for attendance grants, and 614*l.* on results of examination (honours only); total, 86,476*l.*; (*b*) 82,998*l.* to Schools of Science, for capitation and attendance grants and grants on results of examination.

The figures under (*a*) show an average payment in 1898 of 12*s.* 7½*d.* for each individual student under instruction in science schools, whilst the average payment per student under instruction in Schools of Science (*b*) was 3*l.* 18*s.* 2*d.*

The grants now made to schools are based upon the attendance of pupils, instead of being computed on the results of the individual examinations. Referring to this change and to the increase of practical work, Captain Abney, the Director for Science, says:—"In the past year, the system of payments by attendance was made general to all schools except in the case of Schools of Science. From this mode of payment candidates for honours were necessarily omitted, their work being necessarily special and requiring special treatment. The abolition of payments on results has diminished to some extent the numbers of students who were presented for examination, and the course of instruction in the various stages of the subjects of science for which payments are made will be more prolonged. This undoubtedly tends to sound instruction. . . . There is a decided increase in practical instruction in various subjects, and in many places laboratories for physics and for biological subjects have been provided, as the higher attendance grant is only attainable where such provision has been made. I cannot help commenting upon the very marked impression that the obligation to give practical instruction in science has made in the elaboration of apparatus for teaching purposes. At a conference on science teaching, held at the Chelsea Polytechnic under the auspices of the London Technical Education Board, there was an exhibition and demonstration of the use of science apparatus in teaching. The novelties in apparatus and the general interest taken in the conference by science teachers and others clearly indicated the rapid advances that had been made in this branch of teaching"

The Reports of the Inspectors of the Department include many points worthy of the consideration of educationists. The following extracts contain a few of the views expressed on the general subjects of secondary schools and science teaching; and as they represent opinions based upon direct experience of the conditions of elementary scientific instruction in this country, they have exceptional value.

*Extracts from Reports.*

Many of the smaller secondary schools are still badly equipped for teaching purposes. Most of them are ill-supplied with funds, and have consequently an inadequate and inferior staff of teachers, while some few are bent upon continuing methods and subjects of instruction which must be of little value to the class from which their pupils should be drawn. It is, moreover, impossible to deny that owing to the practical absence of outside criticism some few secondary schools are hopelessly inefficient. . . . Many country grammar schools have reason to be thankful to the County Councils for the very liberal aid they have received towards the erection or equipment of suitable rooms for science purposes, or towards the payment of a science master. The County Councils can for their part in most cases ensure that the science work is thoroughly and systematically given by requiring the school to place itself in connection with the Department. To this the best and most progressive of the smaller schools offer no objection. They realise that assistance from public funds must be accompanied by some amount of public control, and as a rule the visit of the inspector is most feared where it is most unknown. Still, in spite of County Council assistance and Department grants, many of the endowed grammar schools are still in straitened circumstances. Where fees are low and endowments small, it is often a serious matter to secure a proper staff of teachers, to keep fittings and apparatus in a proper state of completeness, and to provide for the necessary outlay on repairs, rates and taxes. It is therefore not a matter for surprise if the science and art appliances in some of the secondary schools are found to be meagre in quantity and poor in quality.

On the whole, it may be said that a very fair provision has been made for scientific and technical instruction of the youth of the country up to, at any rate, the age of sixteen or seventeen, supposing them to devote themselves to study until attaining that age, and that in most large towns the artisan and manufacturer can obtain good instruction in technology and general science. But our larger polytechnics could be much further utilised if research work in their laboratories were more encouraged.

It would be most helpful to the technical education of the country if a fairly liberal grant could be paid on any student who, having acquired sufficient training in science, devoted himself to some special work in a laboratory under the supervision of the teacher in charge. The results of such work might be examined and criticised by the professors and examiners of the Department, and, if worthy, brought to the notice of the various societies for the promotion of scientific investigation.

The freedom from examination in the elementary courses of Schools of Science has had considerable influence on the character of the teaching, especially in the practical work. Teachers have awakened to the fact that science may afford a sound mental training, and that method is no less important to a student than results. Syllabuses exhibit a more logical sequence. Instead of depending upon a course thought out by others, teachers are beginning to think out their own, and although there is room for improvement, enlightened methods are making way. The "Heuristic method," which seeks to make each boy or girl a "discoverer" of known physical laws, and thus develop in him the scientific spirit, has had an important influence on the teaching of science. In the hands of a highly competent teacher it is an important guiding principle—in the hands of some of its disciples there is danger of its becoming a fetish. The Heuristic method is essentially historical; the pupil is told little, but is put in the way of finding out for himself, which is well. But there is as much danger in telling him too little as in telling him too much. It is not perhaps impertinent to point out that scientific discoveries have seldom been inductive. Investigators have been acquainted with the results of other discoverers, and have had, almost invariably, a "working hypothesis" which they have sought to establish by deductive methods. It is therefore advisable to lay stress on the usefulness in teaching science of a "working hypothesis," which should form the basis of practical work having for its object the "discovery" of a law. Though the beginner "must be put in the position of an original discoverer," it should be borne in mind that an original discoverer has at his disposal the observations and views of other investigators. It is only fair that the student should be placed in pretty much the same position, otherwise his observations will be ill-directed, and will lead him nowhere. It is almost needless to remark that in any case the advanced work may be more didactic.

## UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

THE natural history collections in the Whitechapel Public Library and Museum are being systematically used by many teachers in the elementary schools of the district to illustrate object lessons. Teachers who propose to utilise the collections for this purpose send to the curator, Miss Kate M. Hall, a list of the object lessons they are giving, and arrangements are then made for one or more practical demonstrations bearing upon the lessons. The children (about forty-five in number) are brought up to the museum every week, for 1 to 1½ hours, until the course is finished. They are divided into three groups of fifteen, and each group spends about twenty minutes at each table on which the specimens chosen for the lesson have been placed. In this way the children have the opportunity of closely observing the objects, and of comparing the structure

with that of other animals or plants. By this means the Library Commissioners are making the collection of real service in elementary education.

The Scottish Education Department has formulated a scheme whereby an agricultural college is to be instituted, to take over the functions of the agricultural department of the Glasgow and West of Scotland Technical College and the Kilmarnock Dairy School. The special grant of 2000*l.* voted for agricultural education in Scotland, and now administered by the Scotch Education Department, has been distributed in various amounts to four institutions, two being those mentioned and the two others the Edinburgh School of Rural Economy and the Agricultural Department of Aberdeen University. It has, however, long been felt that the grants to these institutions ought to be reinforced by contributions from local authorities in order to place the institutions in a position to exercise a more decided influence upon the progress of agriculture in Scotland than has yet been possible. Several County Councils having recently promised support, in some cases of a very substantial kind, to an independent agricultural college in the West of Scotland, the Scotch Education Department prepared a scheme for such an institution, and it has been accepted by the various bodies concerned. The college will give facilities for the most thorough and highly developed instruction in agriculture to those students who are able to devote a considerable time to this study, and should at the same time be a means of bringing home to the agricultural population of the districts concerned the latest results of agricultural research.

The degree of Doctor of Philosophy was conferred in 1898 upon 224 candidates by twenty-three universities in the United States. An analysis of the statistics referring to these doctorates is given in *Science*, together with the names of those who received the degree in science, and the titles of their theses. Of the 224 degrees, 72 were in the humanities (under which are included philology, grammar, literature and philosophy), 37 were in history and economics, and 115 in the sciences. Six universities, Johns Hopkins, Columbia, Yale, Chicago, Harvard and Pennsylvania, conferred 169 degrees—more than three times as many as all the other United States universities combined. Columbia gave this year decidedly the largest number of degrees in the sciences, while Harvard is the only one of these universities in which the degrees in the humanities were more numerous than in the sciences. The distribution of students among the different sciences was as follows:—Chemistry, 32; psychology, 15; mathematics, 13; botany, 11; zoology, 11; physics, 7; education, 5; geology, 5; sociology, 5; palæontology, 4; astronomy, 2; mineralogy, 2; physiology, 1; bacteriology, 1; meteorology, 1. It will be noticed that chemistry leads very decidedly. While no definite conclusion can be drawn from the results, it may be noted that at Johns Hopkins more than half the scientific degrees are given in chemistry. This science also leads at Yale and Harvard. Psychology and education are especially strong at Columbia. Chicago stands first in zoology and in physiology.

The Technical Instruction Committee of the Oxfordshire County Council have presented their annual report on the work of the schools and institutions aided by them during the past year. The Committee has been recognised by the Department of Science and Art as the organisation responsible for science and art instruction within its area. No grants will therefore be made by the Department to the managers of new schools and classes unless they are acting in unison with the Committee. The managers of all the schools and classes in the county which are receiving Science and Art grants have agreed to come within the new organisation. With regard to rural agricultural instruction, the Committee report that at the Chipping Norton Agriculture Class, under Mr. W. Warne, there were seventy-six students, of an average age of 39·5. They were factory hands, labourers, mechanics and small tradesmen, who all cultivated allotments. One thousand and twenty attendances were made at twenty-four meetings. The subject of the course was "Insects as friends and foes to agriculture." To illustrate how agriculture is being gradually develcped by the work of the science lecturers, the Committee report that from advice given by Mr. Stewart, at Minster Lovell, in his lectures, an acre of strawberries was planted. This year a much larger area was laid down there. It is hoped that an industry in soft fruit is now started in that locality. At the same place a fruit farm of three acres was laid out two years ago on Mr. Stewart's advice. It was so successful that now twelve acres are laid out. At Stoke Row, eight tons of filberts last year were saved by the treatment given to the nut weevil, and last year the currant bushes were afflicted by the currant mite, but spraying the bushes enabled four tons to be marketed. Codlin moth and apple-blossom weevil attacked the apple trees, but Mr. Stewart's treatment saved the trees. When agriculturists are brought in this way to see the practical side of scientific knowledge they begin to understand the value of the science of agriculture.

## SCIENTIFIC SERIALS.

*American Journal of Science*, July.—Velocity of electric waves in air, by G. V. Maclean. The author describes an elementary type of coherer suitable for the Hertzian experiment of determining wave-lengths from nodes produced by metallic reflection. It consists of two globules of platinum, 1 mm. in diameter, attached to the ends of two platinum wires forming spirals about two iron terminals which run through the centre of the two brass caps of a glass tube 8·5 cm. long. The globules can be adjusted to any small distance from each other. The velocity of propagation, determined from the wave-length and the period of oscillation, is $2{\cdot}991 \times 10^{10}$ cm. per second, or practically the same as along wires.—Spiral fulgurite from Wisconsin, by W. H. Hobbs. A lightning tube forming a perfect dextrorotary helix has recently been presented to the geological collection of the University of Wisconsin. It was found embedded in a sand knoll about ten feet high, at a distance of five feet below the surface. The tube is as thick as a man's thumb, and five inches long. The fulgurite from Waterville, Maine, described by Bayley in 1892, also shows a dextrorotary structure. The author suggests that this twist is somehow connected with the electrical conditions under which the tubes were produced, and guesses at an influence of the earth's magnetic field upon the path of the lightning.—The mouth of Grand River, by E. H. Mudge. The mouth dealt with is not the present Grand Haven, but another point seventy miles inland from the shores of Lake Michigan, which was the termination of the old river valley. At one time a great glacial stream, three-fourths of a mile in width, flowed across the peninsula from Lake Saginaw to Lake Chicago. This stream has been called the Pewamo outlet. The author describes its course and the river-mouth deposits about the old mouth.—Electrical measurements, by H. A. Rowland and T. D. Penniman. The authors have tested six out of the thirty different methods of measuring self-induction and capacity indicated by Rowland. The methods for the comparison of the two self-inductions, or a self-induction and a capacity, are independent of the period of the alternating current used, and an accuracy of 1 in 10,000 can be attained.—Reflection of Hertzian waves at the ends of parallel wires, by L. de Forest. The author uses a compromise between the Lecher and the Blondlot wire systems, and investigates the relation between the change of phase in reflection from bare ends of various shapes, and the frequency.

*Wiedemann's Annalen der Physik und Chemie*, No. 6.—Observation of fringes in the development of Daguerre plates with wedge-shaped silver iodide layers, by O. Wiener. A silver plate was iodised in two wedge-shaped layers by laying it on a glass tube during exposure to the iodine vapour, the layer thus being made to increase in thickness from the line of contact outwards. A spectrum with the slit normal to the lines of equal thickness was then photographed on the plate, and it was found that the sensitiveness varied periodically with the thickness, maxima occurring whenever the surface coincided with a ventral segment of the electrical force, produced by reflection at the boundary dividing the iodide from the metallic silver.—Experiments on certain flow formations, by K. Mack. Deals with the deformations of fungoid flow structures by gravitation, and the deformation of horizontal layers of liquid by ascending fungoid structures.—Influence of gaseous pressure upon electric currents due to Röntgen rays, by W. Hillers. Near the pressure at which the gaseous resistance reaches a maximum, the current intensity varies as the square root of the pressure.—An electrolytic current interrupter, by A. Wehnelt. This is a reprint of the author's original paper from the *Elektrotechnische Zeitschrift*.—Action of the Wehnelt interrupter, by H. T. Simon. The author formulates what he claims to be a complete mathematical

theory of the Wehnelt interrupter. Between the period T and the E.M.F. E he obtains the relation

$$T = A + \frac{B}{E^2}$$

which is closely borne out by experiment.—Magnetic properties of the elements, by S. Meyer. The author attempts to connect the permeabilities of the elements in the pure state with their atomic weight. When arranged in periodic series, the paramagnetic elements are seen to group themselves in the centre, and the diamagnetic elements at the ends. The scheme is at present very rough, owing to the difficulty of determining the permeabilities of the rare elements —Transverse tones of caoutchouc threads, by V. von Lang. When caoutchouc threads are stretched, the pitch of the note emitted by them remains constant between certain lengths, owing to the fact that the ratio of length to tension is constant. The author investigates how far Taylor's formula applies to such threads.—Accurate control of the frequency of an alternating current, by J. Zenneck. The alternate current is made to produce a rotary field, to which the kathode beam in a Braun tube is exposed. The end of the beam describes a circle on the screen, which is interrupted by a tuning-fork twice during every revolution. As long as the dots thus produced are on the same diameter the frequency is constant.

## *SOCIETIES AND ACADEMIES.*

### PARIS.

**Academy of Sciences**, August 7.—M. Maurice Lévy in the chair.—On rolling motion; equations of motion analogous to those of Lagrange, by M. Appell. The Lagrange equations cannot be applied without modification to those dynamical problems in which the relations between the solid bodies are such that they are allowed to roll or are pivoted on each other. In a system of three independent parameters $q_1$, $q_2$, $q_3$, the equations of motion are reduced to the form $\frac{\partial S}{\partial q_1} = Q_1$, where $Q_1$ is a function of the forces to which the bodies are submitted, and $S = \frac{1}{2}\Sigma m J^2$, J being the acceleration of the point *m*.—Thermochemical determinations: ethylenediamine, by M. Berthelot. Measurements are given for the heats of combustion and formation of cholalic acid, amygdalin, conicine, and ethylenediamine.—On ammoniacal silver nitrate, by MM. Berthelot and Delépine. A thermochemical study of the action of ammonia solution upon a solution of silver nitrate. The oxide of silver-ammonium is shown to be an alkali, with a heat of neutralisation comparable with those of the most energetic mineral alkalis.—On the expansion of iron and steel at high temperatures, by M. H. Le Chatelier. The table of expansions given for soft iron and six specimens of steel, at temperatures ranging between 0° and 700°, shows that the differences in the expansions of the various specimens are within the limits of experimental error; up to about 750°, iron and steel expand similarly. But above the temperature of molecular transformation the expansion of the different specimens of steel varies very rapidly with the amount of carbon present, an increase of carbon from 0·05 to 1·2 per cent. doubling the coefficient of expansion.—Action of chlorine on a mixture of silicon, silica, and aluminium, by M. Émile Vigouroux. A good yield of pure silicon tetrachloride may be obtained by first heating together a mixture of silica (200 gr.) and aluminium (100 gr.) to a dull red heat, cooling the mass and extracting with acids. The residue, thus freed from aluminium, contains from 14 to 22 per cent. of silicon, and readily gives the pure tetrachloride on treating with chlorine in the usual way.—Action of hydrogen phosphide upon copper oxide, hydrate and carbonate, by M. E. Rubénovitch. The reaction with the oxide is energetic, and takes place according to the equation

$$5PH_3 + 10CuO = 2P_2Cu_5 + H_3PO_4 + 6H_2O.$$

Copper hydrate behaves similarly, if the gas is admitted in such small quantities that the temperature of the reaction cannot rise to incandescence. With basic copper carbonate the reaction is

$$5PH_3 + 5CuCO_3.Cu(OH)_2 = 2Cu_5P_2 + H_3PO_4 + 5CO_2 + 11H_2O.$$

—On the estimation of mannose in admixture with other sugars, by MM. Em. Bourquelot and H. Hérissey. The authors apply the property possessed by mannose of giving an insoluble hydrazone in the cold to the estimation of this sugar. The numerous test analyses, some on pure mannose, others on mixtures of the same with galactose and maltose, are very satisfactory.—On some properties of dioxyacetone in respect to its molecular aggregation, by M. Gabriel Bertrand. Dioxyacetone appears to exist in two forms, one in crystals, having a molecular weight $2(C_3H_6O_3)$, which is practically insoluble in cold alcohol, ether, or acetone; the other, formed by simply melting the crystals, has the simple formula $C_3H_6O_3$, and is very soluble in these solvents. Water slowly dissociates the bimolecular form, but not so rapidly as to prevent cryoscopic measurements being made in confirmation of the above views.—On the variations in the production of glycerol during the alcoholic fermentation of sugar, by M. J. Laborde. In the numerous experimental results quoted, the glycerol found varied from 2·5 to 2·75 grams of glycerine per 100 grams of sugar decomposed. The same yeast, living in saccharine media of the same concentration of sugar, may give very varying amounts of glycerol, the production being in inverse proportion to the activity of the yeast. A rise of temperature favours an increase in the amount of glycerol.—On the anatomical structure of *Vanilla aphylla*, by M. Édouard Heckel. A comparison of the anatomical characters of the stems of *V. aphylla* and *V. phalaenopsis* shows such great differences that it is impossible to class them together in the same genus. The author also points out that the theory adopted by Herbert Spencer, in his "Principles of Biology," to explain the formation of monocotyledonous stems, is strongly supported by the fact of the simultaneous presence in the stem of *V. aphylla* and the leaves of *V. phalaenopsis* of the same cellular elements constituting the skin.—The *Piralahy*, the india-rubber weed of Madagascar, by M. Henri Jumelle.—On the external border of the Briançonnais between Freyssinières and Vars, by MM. W. Kilian and E. Haug.—On the pot-holes of the granitic islets of the cataract of Assouan, by M. Jean Brunhes.

## THE BOOK OF THE DEAD.

*The Book of the Dead. Facsimiles of the Papyri of Hunefer, Ånhai, Kerāsher and Netchemet, with Supplementary Text from the Papyrus of Nu, with Transcripts, Translations, &c.* By E. A. Wallis Budge, M.A., Litt.D., D.Lit., Keeper of the Egyptian and Assyrian Antiquities, British Museum. Pp. xi + 64 (fol.) + 98 plates. Printed by order of the Trustees. (London, 1899.)

SINCE the beginning of the present century the "Book of the Dead" has occupied the attention of the learned world, and has been a subject of study among all those who take an interest in the religious beliefs of the ancient races of mankind. The earliest publications on the subject took the form of somewhat inaccurate reproductions of papyri on which the text of the "Book of the Dead" was written; and, though much speculation existed as to the nature of its contents, it was not until well on in the present century that the foundations were laid for its correct interpretation. Champollion had made careful studies of the whole of the texts of the "Book of the Dead" to which he had access; and, from the translations of detached passages which are found scattered in his writings, it is clear that he recognised the general character of the composition. But he never translated a section of any length, and the fact that he termed the "Book of the Dead" "le Rituel Funéraire" of the Egyptians showed that he had not correctly grasped its aim and object. More than thirty years later De Rougé adopted Champollion's title for the work, but since that time it has come to be recognised by all that the composition is not a collection of ritual texts, and that a more general phrase such as "Book of the Dead" is a more suitable title for the work.

The title "Book of the Dead" may be traced to Lepsius, who in 1842, under the heading "Das Todtenbuch der Aegypter" published the text of a papyrus at Turin, which contained one hundred and sixty-five sections or chapters of the work. The ancient Egyptians themselves did not number these chapters, and no two papyri contain exactly the same chapters, nor are they always arranged in the same order. Lepsius, however, numbered the chapters as he found them in his papyrus, and though the text he published does not belong to the best period of the development of the "Book of the Dead," his numbering of the chapters has been retained in subsequent editions of the work. It was retained by M. Naville in his great work on the papyri of the eighteenth to the twentieth dynasties, which was published in 1886; and it has also been retained in the recent important publications issued by the Trustees of the British Museum.

In order to indicate clearly the importance of the volume before us, it will be necessary to give a brief account of what the "Book of the Dead" is. It consists of a collection of chapters or separate compositions of different lengths, which are found in Egypt inscribed upon pyramids, upon the walls of tombs, upon sarcophagi, and coffins, and amulets that were buried with the dead; it is also found written upon long rolls of papyri which were placed in the tomb with the deceased. Stated briefly, the object of all these compositions was to ensure the preservation of the dead man's body and to secure his welfare in the world beyond the grave. Dr. Wallis Budge has recently put forward a theory as to the process by which such powers became ascribed to this collection of compositions, which are conveniently classed together as the "Book of the Dead." He has pointed out that in the earliest period of Egyptian civilisation the dwellers on the Nile, as is evident from recent excavations, were in the habit of carefully preserving the dead bodies of their friends and relatives. Even at this early period it is clear that the Egyptian hoped to live a life after death, and that the life he looked forward to he imagined would be very similar to that he lived on earth; and it is also clear that to attain this future life he believed that it was absolutely necessary to preserve his body from decay. The earliest graves in Egypt show that the Egyptians of that period, like their descendants of later date, endeavoured to attain to the future life by the embalming of the body. The recently excavated prehistoric graves, in which, along with flints, bronze implements and pottery, the skeletons of human bodies have been found lying on their sides with their knees bent up on a level with the chest, furnish evidence that even at the dawn of history the inhabitants of Egypt embalmed their dead; for many of the bones found in the graves show traces that the bodies to which they belonged had been treated with substances used in embalming. But it was clear to the ancient Egyptian that bodies, even when embalmed, were accessible to the attacks of foes and to the ravages of wild beasts. And so, in course of time, men raised pyramids about the dead to protect them, or buried them in chambers hewn out of the living rock. But the most carefully constructed tomb could not wholly prevent decay, and there was always danger of damp getting to the tomb, or of the body falling to pieces from dry-rot. According to Dr. Budge's theory, the Egyptian now called in some other power besides his own to prevent the destruction of the body, and, while he still continued to embalm his dead, he assigned to the priest the task of finding some means by which decay might be prevented. To attain this end the priest pronounced certain words and formulæ over the body. These formulæ, Dr. Budge considers, formed the foundation of the "Book of the Dead" of later times. As was but natural, they gradually increased in number and complexity, and developed with the changing civilisation of the race; with them were incorporated beliefs belonging to various periods in the long course of Egyptian history, and opinions held by quite different schools of thought. But the object of all these various compositions was the same, namely, to benefit the deceased man beyond the grave. They were intended to give him all he would want in the future life, they would ensure him victory over his foes, and they would enable him to safely reach the abode of the blessed, where he hoped to live happily in the future.

The importance of a careful and comparative study of these numerous forms of the "Book of the Dead" for a

right understanding of the religion of the ancient Egyptians is obvious, and the first step towards such a comparative study is to acquire all texts available for the purpose and to make them accessible to the numerous students, who in England, and on the continent, and in America are now devoting so much time and labour to the comparative study of religion. For many years the Trustees of the British Museum have had this object in view, and they have issued a most important series of facsimiles and works dealing with the "Book of the Dead"; the series was begun under the editorship of the late Dr. Birch, and has recently been continued under that of Dr. Wallis Budge, who has succeeded him in the keepership of the Egyptian and Assyrian antiquities at Bloomsbury. Of these publications, the "Egyptian Texts from the earliest period from the Coffin of Āmamu," which were published in facsimile with a translation by Dr. Birch, belong to the recension of the "Book of the Dead" which is found written upon coffins during the eleventh and twelfth dynasties; while the "Photographs of the Papyrus of Nebseni" placed in the hands of scholars one of the finest and most complete texts of the Theban recension of the work then known. In the year 1888 Dr. Wallis Budge, while in Egypt, acquired for the Trustees the famous Papyrus of Ani, which, dating from the second half of the eighteenth dynasty, is the most perfect and best illuminated of all papyri of the "Book of the Dead." Two years after its discovery it was published in facsimile, and in 1895 a second edition of the facsimile was issued, together with a translation and introduction from the pen of Dr. Budge. The texts thus published illustrate the history of the "Book of the Dead" in the period which lies between B.C. 2600 and B.C. 1700.

The volume just issued by the Trustees supplements these previous publications. It is larger than any of its predecessors, giving facsimiles, transcripts, translations, &c., of no less than five complete papyri of the "Book of the Dead," including a copy of the "Book of Breathings," a late form of composition to which the "Book of the Dead" was eventually reduced. These documents are all fine examples of the work, and they date from the beginning of the eighteenth dynasty to the end of the Ptolemaic period, that is, from about B.C. 1650 to B.C. 100. The series of publications on the "Book of the Dead," that has been issued by the Trustees at intervals during the last thirty-three years is therefore now complete.

In describing the contents of the volume it will not be possible within the limits of this review to do more than indicate roughly the general characteristics of the various papyri and the bearings each one has on the problems connected with the history and development of the great funereal work of the Egyptians. The first papyrus in the volume is that of Hunefer, an overseer of the palace and superintendent of the royal cattle, and "royal scribe" in the service of Seti I., King of Egypt about B.C. 1370. It is not a very long papyrus, but its vignettes are singularly beautiful. No other papyrus of the nineteenth dynasty is so finely illustrated, and as an artistic work it may be said to rank very little below the Papyrus of Ani. Perhaps the most interesting of the larger vignettes is the scene before the tomb on Plate 7. By the door of the tomb is set the sepulchral tablet of the deceased, and in front is seen the mummy of Hunefer, supported by the jackal-headed Anubis, one of the chief gods of the dead, who presided over the embalming of the mummy and accompanied the deceased into the presence of Osiris. Hunefer's wife and daughter kneel weeping at the mummy's feet, while behind are three priests performing ceremonies for the dead man's benefit and burning incense. Of the smaller vignettes the most interesting is the one at the very end of the papyrus, attached to Chapter xvii. (Plate 11); the vignette represents a cat, in front of the Persea tree, cutting off the head of a serpent, and symbolises the rising sun-god slaying the dragon of darkness—a legend that finds a place in the mythology of many other races.

The second papyrus in the volume is that of a lady named Ȧnhai, who was attached to the college of Ȧmen-Rā at Thebes, and who lived at the end of the twentieth or at the beginning of the twenty-first dynasty, *i.e.* about B.C. 1100. The vignettes are of an unusual character, and show that under the influence of the priests of Ȧmen the "Book of the Dead" was illustrated with scenes which do not belong to it by right, but are drawn from other works dealing with the Underworld. Of the vignettes an interesting one (Plate 6) shows the lady Ȧnhai binding up bundles of wheat and performing other duties in the Elysian fields. Another vignette represents the creation of the universe (Plate 8), and is an interesting variant to the similar scene depicted on the sarcophagus of Seti I. The third papyrus is that of Netchemet, who was in all probability the daughter of the priest king Ḥer-Ḥeru-sa-Ȧmen, who ruled over Egypt about B.C. 1000. This papyrus is inscribed in hieratic, and as it has not the beauty of colouring of the two first papyri in the volume, it has been reproduced in a series of half-tone blocks. The papyrus of Kerāsher, the fourth in the volume, is inscribed with a copy of the "Book of Breathings," a late form of the "Book of the Dead," dating from the late Ptolemaic or Roman period.

So far as the text of the "Book of the Dead" is concerned, by far the most valuable of the five papyri is the last in the volume, for it contains a number of chapters that have not hitherto been found in the Theban Recension, in addition to a good deal of rarely-found as well as quite new material. Nu was an officer in the house of the overseer of the Chancery, and the son of Ȧmen-hetep, and the papyrus dates from about B.C. 1650. It is the oldest illustrated copy of the "Book of the Dead" that is known.

We have only been able to give the briefest sketch of the contents of this very valuable book, but what we have said will suffice to indicate its importance, inasmuch as it presents a mass of new material for the study of the ancient Egyptian religion. Moreover, two out of the five papyri are written in the hieratic character, which of course is a sealed script to all but a few experts. Dr. Budge, however, has furnished them with transcripts into hieroglyphics, so that the book may be used as a chrestomathy by those who would acquire a knowledge of this interesting but difficult form of Egyptian writing. Of the value and interest of Dr. Budge's introductions and translations, appended to the various papyri, it is unnecessary to speak at length, for even before the publication of this work

no other living scholar had done more than he for the study of the "Book of the Dead," both by the publication of new material and by the interpretation and translation of the entire work. The present volume is unique in its own sphere, and no private individual or firm of publishers could have undertaken the responsibility of such a production. The Trustees have earned the gratitude of scholars by making so much new material available for general study, and they are to be congratulated on the production of a monumental work which worthily carries on the scholarly traditions attaching to the Museum at Bloomsbury.

## HAMILTON'S QUATERNIONS.

*Elements of Quaternions.* By the late Sir W. R. Hamilton. Second edition. Vol. I. Edited by C. J. Joly. Pp. xxxiii + 583. (London: Longmans, Green, and Co., 1899.)

FOR many years Hamilton's "Lectures" and "Elements" have been out of print, and the ardent student of quaternions was oftentimes unable to secure a copy of either of these great classics. Prof. Tait's treatise on quaternions is probably a better introduction for the beginner, who is more quickly brought into touch with the essential spirit of the method than he would be in Hamilton's pages. But he must, some time or other—unless he be a second Hamilton—bathe his mathematical being in the inexhaustible streams of quaternion analysis and symbolism that flow from the great master's mind. A second edition of Hamilton's immortal work is therefore to be warmly welcomed. English-speaking students will now be able to study Hamilton freely without having recourse to French or German translations; and it is our hope that the issue of this second edition will lead to a wider appreciation of the value of quaternions as a mathematical method peculiarly adapted to the geometry of space and general problems in dynamics.

The new edition is printed by direction of the Board of Trinity College, Dublin, and is edited by Prof. Joly. In the larger size of page and larger and wider type there is a great improvement on the original form, although it has necessitated dividing the book into two volumes. The small print has been done away with altogether. This, in itself, no doubt is better for the reader; but the advantage is lost that he can no longer discern at a glance what is illustration and particular from what is general and fundamental. For example, in the very important sections on the linear and vector function, one of the most beautiful of Hamilton's creations, the reader cannot pick out so readily as in the original edition the broad line along which the fundamental properties of this function are developed. Many of the illustrations are really of the character of examples, such as Prof. Tait puts at the end of his different chapters. Printing these in the same style as the more important parts tends to give them a fictitious value, and to blurr the whole perspective of the book.

The editor has added occasional notes to elucidate points which might appear obscure to the student. In some of these a different line of proof may be suggested, or they may simply amount to a reference to another section. Prof. Joly has exercised this editorial function with judgment. One of the longest of these notes is appended to the chapter on the well-known $i, j, k$ relations, and brings out clearly the necessity for the negative sign of the square of a vector, *if the associative law in products is to hold.* The system which is built on the assumption that $i^2=j^2=k^2=+1$ is ascribed to Mr. Oliver Heaviside. It ought, strictly speaking, to be ascribed to O'Brien, a contemporary of Hamilton's.

We are not called upon at this date to consider the merits of Hamilton's great calculus. The objections taken to it by mathematicians great and small have been so curious and, in some cases, so puerile that we doubt if these critics have ever seriously set themselves to study its true character. One really eminent mathematician who had been fortunate enough to pick up a copy of Hamilton's "Lectures" for a trifling sum, gladly transferred his prize next day to a friend, remarking that the man must have been mad who invented quaternions, for he made two sides of a triangle equal to the third side! Maxwell adopted the compact suggestive notation in his "Electricity and Magnetism"; and many of the transformations which are so necessary now-a-days in connection with electromagnetic waves, and take a page or two to effect in ordinary notation, are done almost by inspection by quaternion methods. Maxwell did not use the quaternion method, not because he regarded it as inferior to the notation, as one writer has with curious logic argued, but simply because the world was not ready for it. Let us hope that with this handsome re-issue of one of the most characteristic works of our century a renewed interest will be taken in the study of quaternions, so that in the near future operations and notations alike may be freely used in works on mathematical physics. Prof. Joly deserves the gratitude of all for his labour of love. When we remember the peculiar characteristics of Hamilton's style, with its redundant italics and capitals, we realise the hardness of the task the editor has set himself in reproducing to the letter (barring misprints) this great monumental work.

One word in conclusion. Is no new edition of the "Lectures" to be brought out—or at any rate of Lecture vii., which is nearly as long as the other six put together? A re-issue of Lecture vii., with perhaps an introductory chapter giving the fundamental principles of the calculus, would confer a boon on many students. In this so-called "Lecture," the great mathematician moves with a giant stride over the greater part of the whole field of geometry and dynamics. From it alone Tait drew his inspiration.

C. G. K.

## OUR BOOK SHELF.

*A Short History of the Progress of Scientific Chemistry in our own Times.* By Prof. W. A. Tilden. Pp. x + 276. (London: Longmans, Green, and Co., 1899.)

IN size and scope Prof. Tilden's short history recalls Wurtz' brilliant little "History of Chemical Theory," published thirty years ago. But whereas the key-note of Wurtz' book was the "immortal memory" of Lavoisier, and its main theme the vindication of French chemists *contra mundum*, the spirit of Dr. Tilden's book lies in its impartiality and sound judgment. In mode of

treatment, too, the authors differ. Wurtz, with more personal touches and controversial points, traces the main ideas of chemical combination from the time of Lavoisier continuously to his own; Prof. Tilden, adopting the more natural lecture method, has given us separate histories of the main lines of chemical progress during the Victorian era. We cannot doubt but that the student will find the modern book handier to consult, and sounder, though possibly less stimulating, than its predecessor.

The difficult task of selection has been, on the whole, successfully met by Prof. Tilden. We can heartily commend for its lucid treatment the chapter on stereochemistry, and "the classification of the elements" for its historical completeness and common sense.

The few slips we have observed are mainly printer's errors, *e.g.* the date of the "Sceptical Chymist" is given as 1680 (p. 38). In the account of Dumas' experiments on the composition of water, we are told that the retention of hydrogen by the reduced copper was unsuspected in Dumas' time (p. 80); but Dumas himself refers to this error in his original paper. Prof. Tilden repeats the usual derivation of gas, "Gas = geist = spirit." But since the publication of "Gas" in Dr. Murray's Dictionary we thought the derivation from chaos had been accepted. Perhaps we may quote the full passage from Van Helmont, which occurs in the "Progymnasma Meteori" (p. 69, ed. 1682): "Verum quia aqua in vaporem, per frigus delata, alterius sortis, quam vapor per calorem suscitatus; ideo paradoxi licentia, in nominis egestate, halitum illum gas vocavi non longe a Chao veterum secretum."

*La Géologie Expérimentale.* Par Stanilas Meunier, Professeur de Géologie au Muséum d'histoire naturelle de Paris. Avec 56 figures dans le texte. Pp. 306. (Paris: Félix Alcan, 1899.)

IN this work, which has just been added to the "Bibliothèque Scientifique Internationale," Prof. Meunier has aimed at supplying a complete and practical series of experimental illustrations of as many different geological phenomena as possible — in this respect going even farther than did the late M. Daubrée in his classical "Études Synthétiques de Géologie Expérimentale." The work is founded on a course of lectures given in Natural History Museum of Paris in 1898; and in the Geological Gallery of the Museum in the Jardin des Plantes may be seen the actual apparatus, designed by the author and others, for carrying on the experiments described in these pages.

After a general introduction on the value and limits of the experimental method as applied to geological teaching and research, in which the author replies very effectively to the objections which have been raised to it, he proceeds to treat systematically with the questions involved in supplying experimental illustrations of geological phenomena. He first deals with the results produced by the action of external forces operating on the earth's crust. These are classed as the phenomena of denudation and of sedimentation. Under the first head are classed the action of rain, of rivers, of the sea and lakes, of ice, of subterranean waters and of the wind. It is noticeable that the experiments, many of which are of a novel character, are for the most part such as can be performed with very simple apparatus, of a kind which any ingenious lecturer may readily provide himself with at a relatively small cost, and the experiments are certainly calculated to give point and value to the teaching they are intended to illustrate. The various kinds of sedimentation are treated of in the same way, the action of rain, rivers, seas and lakes, subterranean waters and wind in accumulating materials to form new rocks being successively handled. In the second part of the work we have a series of experiments to illustrate the action of the internal forces at work on the earth's crust. The origin of crystalline rocks, including illustrations of vitrification and devitrification, metamorphism, both contact and regional, and the origin of mineral veins are discussed in a somewhat summary manner, with reference chiefly to work that has been carried on in France; and this division of the book ends with a rather speculative chapter on the more deeply-seated materials of the globe. The third part of the work deals with volcanoes, earthquakes and the production of mountain-chains. Although the treatment of the various questions is—perhaps necessarily—somewhat unequal, no teacher of geology can fail to gather from this work of Prof. Meunier many useful hints which will prove of great value in illustrating the action of the various forces which have contributed to the production of the features of the earth's crust, while the student and general reader will find it equally full of suggestiveness and novelty.

*The Fauna of Shropshire: being an Account of all the Mammals, Birds, Reptiles and Fishes found in the County of Salop.* By H. E. Forrest. Pp. viii + 248 + vi; illustrated. (Shrewsbury and London, 1899).

THIS little book, excellent in its way as a local vertebrate fauna, is somewhat more than its title implies. It gives, for instance, a very well-written and interesting account of the habits of many species of British mammals, more especially the smaller and commoner kinds. Particular attention may be directed to the life-histories of the mole and the shrew, some of the facts in the former being new to us. The great feature of the book is the very excellent account of the mode of development and general habits of the British Amphibia; this group of animals being apparently the author's favourite subject of study. The reptiles are treated nearly as fully as the frogs and newts; and here we may notice that the author considers that the legend of the viper's swallowing its young may prove to be based on fact. A much smaller proportionate amount of space is devoted to the birds, for the reason that the author hopes to elaborate this portion of his subject on a future occasion.

Although the illustrations, which are chiefly taken from mounted groups, are less satisfactory than they might be, the work may be commended not only to the naturalists of Salop, but to those of the British Islands generally.

R. L.

*La Pratique du Maltage.* Par Lucien Lévy. Pp. 248. (Paris: G. Carré et C. Naud, 1899.)

THIS work, which may be classed as belonging to the best type of modern technical literature, is based on a series of lectures given by Prof. Levy at the "Institut des Fermentations de l'Université Nouvelle" of Brussels. At present there is a very open field for such a book, for during recent years no other work devoted specially to malting has been published which attempts, like the one before us, to combine the scientific and practical sides of the question. The work will have most value to readers in this country for the very complete account it contains of recent scientific work connected with germination; this is given in a very clear and concise form, and the most recent researches of any importance are referred to. The more technical portions of the book bear a continental stamp, and in certain places lead us to think that there are some things connected with malting we do better in England. However this may be, the work as a whole is recommended to those interested in malting as the best technical treatise on the subject at present published; but it should be borne in mind that it is specially

written for students on the continent, where the method of malting differs somewhat from ours. The printing, paper, and binding of the book are particularly good.

A. J. B.

*Curiosities of Light and Sight.* By Shelford Bidwell, M.A., LL.B., F.R.S. Pp. xii + 226. (London: Swan Sonnenschein and Co., Ltd., 1899.)

MANY readers will be glad to possess this collection of essays, in which Mr. Shelford Bidwell describes some of the experiments which the scientific world owes to his ingenuity. The five chapters in the volume are based upon notes of lectures delivered to various audiences; and their subjects are: light and the eye, colour and its perception, some optical defects of the eye, some optical delusions, and curiosities of vision. Each subject is presented with freshness of style, and elucidated by many simple and convincing experiments. To the popular lecturer on science, who desires to know how to produce curious and instructive optical effects, the volume will be very acceptable, and every physical experimentalist may confidently turn to it for inspiration. But though the curiosities of colour phenomena, and of sight generally, are chiefly described in the book, many questions of deep interest to students of both physical and physiological optics are discussed, so that the volume appeals to scientific as well as popular readers.

## LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

### A Curious Salamander.

THE artificial propagation of food fishes is an important part of the work of the United States Fish Commission, and for this purpose it has a number of hatcheries or "stations" scattered throughout the Union. At each of these stations especial attention is given to the rearing of the fishes best adapted to the region in which that particular station is placed, as it would be useless to breed salmon or trout for the warm, sluggish streams of the South, or to put bass and carp into the cold, swift rivers of New England or of Michigan. The sea stations are devoted to the study of marine zoology, and the propagation of shad, mackerel, cod, lobsters and similar organisms that cannot be bred in fresh water; while hatcheries have been put on the banks of several lakes at which whitefish, land-locked salmon, lake trout and the like are reared.

A few years ago a station was established near the town of San Marcos, Texas, for the culture of black bass and "crappies." A prime essential for fish hatching is a copious supply of water, and the supply should be as uniform in amount, temperature and composition as it is possible to obtain. If there be much sediment in the water, it will be deposited on the eggs and suffocate them; and sudden variations in temperature may also be fatal. As the rainfall in western Texas is untrustworthy, the Commission determined to bore an artesian well to supply the water for its new station.

The well was bored successfully and a flow of twelve-hundred gallons per minute obtained from a depth of 188 feet. There are several such wells in this region that give this amount or more, but soon after the San Marcos well was opened a number of living animals began coming up with the water. So far, four kinds of Crustacea and a salamander have been seen, and of these quite a number have been obtained. The Crustacea are new to science and were described by Dr. James E. Benedict, of the Smithsonian Institution. They are white and perfectly blind. Most of the shrimps and crab-like animals have eyes set on the extremities of stalks that project above the surface. The shrimps from this well have the stalks, but the eyes have disappeared.

The most remarkable creature that has come from the well is the blind salamander, the *Typhlomolge Rathbuni*. The name

FIG. 1.—*Typhlomolge Rathbuni*, seen from above. (Photographed by W. P. Hay.)

is compounded from the Greek *typhlos*, blind, and *molge*, a kind of salamander; while the second term was given in honour of Mr. Richard Rathbun, the Assistant Secretary of the Smithsonian Institution, and for many years the Chief of the Division

FIG. 2.—*Typhlomolge Rathbuni*, $\frac{3}{4}$ life. (Photographed by W. P. Hay.)

of Scientific Inquiry of the Fish Commission. This animal is a new species and a new genus. It was described by Dr. L. Stejneger, of the Smithsonian Institution. The *Typhlomolge* is from three to four and a half inches in length. It has a large head, protruding forward into a flattened snout that bears the mouth. The eyes are completely covered by the skin, and are visible from the outside only as two black specks. Just behind the head are the gills. These are external and stand out in festoons about the neck, instead of being covered by a lid as in fishes. The skin is a dingy white, and the sharp contrast between

the colourless skin and the vivid scarlet of the exposed gills makes the appearance of this subterranean visitor striking in the extreme. It has four long, slender legs, that are gruesomely human in appearance, and are supplied with feet that are startlingly hand-like. The fore feet bear four fingers or toes and the rear ones have five, and though the legs are extremely slender, they possess a considerable amount of strength. Behind, the body terminates in a flattened tail that bears a fin like that of an eel.

In April 1899, two living specimens of this strange being were shipped by mail from San Marcos to the head office of the Fish Commission in Washington. They bore the journey of nearly 1800 miles, and reached their destination in good condition. They excited great interest, and for some time after their arrival a wondering group of spectators crowded about the aquarium into which they were put. These living specimens corrected several errors that had been made from observations of the dead bodies only. The legs are used for locomotion, and the animals creep along the bottom with a peculiar movement, swinging the legs in irregular circles at each step. They climb easily over the rocks piled in the aquarium, and hide in the crevices between them. All efforts to induce them to eat have been futile, as has also been the case with blind cave fish in captivity and they are either capable of long fasts or live on infusoria in the water.

From whence do these strange creatures come? The well is sunk in limestone, and that renders it likely that there may be some great cavern or subterranean lake communicating with it, but the rock through which the hole is bored is solid, except for a single channel two feet in diameter. The fact that the water rises nearly two hundred feet shows it to be under great pressure, and altogether this well affords material for study to geologists as well as zoologists.

Washington, D.C. CHARLES MINOR BLACKFORD.

## Palæolithic Implement of Hertfordshire Conglomerate.

THE rudely-made Palæolithic implement, illustrated to half the actual size in the accompanying engraving, is probably unique in the highly intractable material from which it is made. It was found by me in May last with Palæolithic implements of flint in the Valley of the Ver, Markyate Street, near Dunstable: its weight is 1 lb. 6¼ oz.—1677 in my collection. Although rude, there is no doubt whatever as to its true nature; there is a large bulb of percussion on the plain side, as seen in the edge

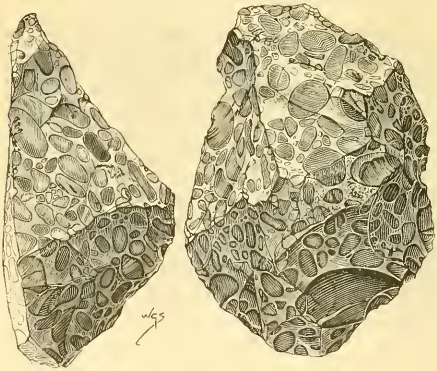

FIG. 1.—Palæolithic implement of Hertfordshire Conglomerate. One-half actual size.

view, and the hump-backed front is chipped to a rough cutting edge all round, each facet going right through the embedded pebbles. Its condition is totally different from a newly-broken block of Conglomerate, and indeed of Conglomerate broken in Roman times by quern-makers. It is faintly ochreous from being long embedded in clay, and sub-lustrous. Newly-broken Conglomerate is in colour a lustreless cold grey. The peculiar nature of the material would not admit of finer work: I have tried hard to flake Conglomerate without the slightest success; it breaks only after the heaviest blows, and then in the most erratic manner, the embedded pebbles often flying from the matrix. Sir John Evans has seen this example, and agrees with my conclusions as above expressed; he also informs me that several years ago he found what appears to be the point of a lanceolate implement of the same material and of Palæolithic character on the surface of a field near Leverstock Green.

Dunstable. WORTHINGTON G. SMITH.

## On the Calculation of Differential Coefficients from Tables Involving Differences; with an Interpolation-Formula.

(1) IN NATURE for July 20 (p. 271) Prof. Everett has given formulæ for calculating first and second differential coefficients in terms of differences. The formulæ can be more simply expressed in terms of "central differences." Let the values of a function $u_x$ be given for $x = \ldots, -2, -1, 0, 1, 2, \ldots$; then, with the usual notation,

$$\Delta u_0 = u_1 - u_0$$
$$\Delta^2 u_0 = \Delta u_1 - \Delta u_0 = u_2 - 2u_1 + u_0,$$
&c.

Now write

$$\begin{aligned} \tfrac{1}{2}(\Delta u_0 + \Delta u_{-1}) &= a_0 \\ \Delta^2 u_{-1} &= b_0 \\ \tfrac{1}{2}(\Delta^3 u_{-1} + \Delta^3 u_{-2}) &= c_0 \\ \Delta^4 u_{-2} &= d_0 \end{aligned}$$
&c.

Then $a_0, b_0, c_0, d_0, \ldots$ are the "central differences" of $u_0$. Take, for instance, the following table:—

| $y$ | $e^y$ | $\Delta$ | | | |
|---|---|---|---|---|---|
| 4·7 | 109·947 | | | | |
| | | 11563 | | | |
| 4·8 | 121·510 | | 1217 | | |
| | | 12780 | | 126 | |
| 4·9 | 134·290 | | 1343 | | 17 |
| | | 14123 | | 143 | |
| 5·0 | 148·413 | | 1486 | | 12 |
| | | 15609 | | 155 | |
| 5·1 | 164·022 | | 1641 | | 19 |
| | | 17250 | | 174 | |
| 5·2 | 181·272 | | 1815 | | 15 |
| | | 19065 | | 189 | |
| 5·3 | 200·337 | | 2004 | | 24 |
| | | 21069 | | 213 | |
| 5·4 | 221·406 | | 2217 | | 18 |
| | | 23286 | | 231 | |
| 5·5 | 244·692 | | 2448 | | 28 |
| | | 25734 | | 259 | |
| 5·6 | 270·426 | | 2707 | | |
| | | 28441 | | | |
| 5·7 | 298·867 | | | | |

Writing $y = 5{\cdot}2 + {\cdot}1x$, and $u_x = 10^3 e^y$, so as to get rid of decimals, we have the following values corresponding to $y = 5{\cdot}2$ $(x = 0)$:—

| $u_0$ | $a_0$ | $b_0$ | $c_0$ | $d_0$ | $e_0$ |
|---|---|---|---|---|---|
| 181272 | 18157½ | 1815 | 181½ | 15 | 2½ |

With this notation, the value of $u_x$ for values of $x$ between $-\frac{1}{2}$ and $+\frac{1}{2}$ is given by

$$u_x = u_0 + xa_0 + \frac{x^2}{2!}b_0 + \frac{x(x^2-1)}{3!}c_0 + \frac{x^2(x^2-1)}{4!}d_0 + \frac{x(x^2-1)(x^2-4)}{5!}e_0 + \ldots\ldots \quad \text{(i.)}$$

This is a well-known formula. Differentiating with regard to $x$, and putting $x = 0$, we have (writing $u$ for $u_x$)

$$\left(\frac{du}{dx}\right)_0 = a_0 - \tfrac{1}{6}c_0 + \tfrac{1}{30}e_0 - \tfrac{1}{140}g_0 + \ldots\ldots \quad \text{(ii.)}$$

Similarly, differentiating twice, and putting $x = 0$,

$$\left(\frac{d^2u}{dx^2}\right)_0 = b_0 - \tfrac{1}{12}d_0 + \tfrac{1}{90}f_0 - \tfrac{1}{560}h_0 + \ldots\ldots \quad \text{(iii.)}$$

Prof. Everett's formula for the "increase-rate" when fifth differences are negligible is obtained by taking the first two terms of (ii.).

(2) The advantage of these formulæ, as Prof. Everett points out, is their greater accuracy. The ordinary formula

$$\Delta - \tfrac{1}{2}\Delta^2 + \tfrac{1}{3}\Delta^3 - \tfrac{1}{4}\Delta^4 + \tfrac{1}{5}\Delta^5,$$

in the above example, would give for $y = 5{\cdot}2$

$$\frac{du}{dx} = 18131\tfrac{1}{2},$$

while, if the differences were taken backwards, we should get

$$\frac{du}{dx} = 18124\tfrac{1}{5}.$$

The formula (ii.), taken to the fifth central difference, gives

$$\frac{du}{dx} = 18127\tfrac{1}{3},$$

the true value being

$$\frac{du}{dx} = 18127{\cdot}224.$$

The inaccuracy in the ordinary formula is, of course, due to the fact that a table such as the above never gives the exact value of the function tabulated, but only the nearest integral multiple of a certain unit (in this case ·001). If we denote this unit by $\rho$, each tabulated value differs from the true value by some quantity lying between $-\frac{1}{2}\rho$ and $+\frac{1}{2}\rho$. It may be shown that this makes it possible for $\Delta - \frac{1}{2}\Delta^2 + \frac{1}{3}\Delta^3 - \frac{1}{4}\Delta^4$ to differ from its true value by as much as $\frac{16}{3}\rho$, while $a_0 - \frac{1}{6}c_0$ cannot differ from its true value by more than $\frac{3}{4}\rho$. Hence this latter formula is more accurate than the ordinary one in the ratio of 64 : 9, or about 7 : 1, when fifth differences are negligible. When only seventh differences are negligible, the formula $a_0 - \frac{1}{6}c_0 + \frac{1}{30}e_0$ is more accurate than the ordinary formula, in the ratio of 832 : 55, or about 15 : 1.

(3) The formulæ (ii.) and (iii.) give the first and second differential coefficients for the values of the "argument" shown in the table. It is often more useful to have them for the *intermediate* values. This requires a modification of the method of central differences. Let us write

$$\begin{aligned}
\tfrac{1}{2}(u_1 + u_0) &= \mathrm{V} \\
\Delta u_0 &= \Delta_1 \\
\tfrac{1}{2}(\Delta^2 u_0 + \Delta^2 u_{-1}) &= \Delta_2 \\
\Delta^3 u_{-1} &= \Delta_3 \\
&\text{\&c.}
\end{aligned}$$

Thus for the interval from 5·2 to 5·3, in the above example, we have

| V | $\Delta_1$ | $\Delta_2$ | $\Delta_3$ | $\Delta_4$ | $\Delta_5$ |
|---|---|---|---|---|---|
| $190804\frac{1}{2}$ | 19065 | $1909\frac{1}{2}$ | 189 | $19\frac{1}{2}$ | 9 |

With this notation, it may be shown that, for any value of $x$ from 0 to 1,

$$\begin{aligned}
u_x = &\left\{\mathrm{V} - \frac{1-2x}{2}\Delta_1\right\} \\
&- \frac{x(1-x)}{2\,!}\left\{\Delta_2 - \frac{1-2x}{6}\Delta_3\right\} \\
&+ \frac{x(1-x^2)(2-x)}{4\,!}\left\{\Delta_4 - \frac{1-2x}{10}\Delta_5\right\} \\
&- \frac{x(1-x^2)(4-x^2)(3-x)}{5\,!}\left\{\Delta_6 - \frac{1-2x}{14}\Delta_7\right\} \\
&+ \ldots\ldots\ldots\ldots\ldots\ldots \quad \text{(iv.)}
\end{aligned}$$

Or, if we write $x = \frac{1}{2} + \theta$, then for values of $\theta$ from $-\frac{1}{2}$ to $+\frac{1}{2}$,

$$\begin{aligned}
u_{\frac{1}{2}+\theta} = &\{\mathrm{V} + \theta\Delta_1\} \\
&- \frac{1-4\theta^2}{2^2.2\,!}\left\{\Delta_2 + \tfrac{1}{3}\theta\Delta_3\right\} \\
&+ \frac{(1-4\theta^2)(9-4\theta^2)}{2^4 \cdot 4\,!}\left\{\Delta_4 + \tfrac{1}{5}\theta\Delta_5\right\} \\
&- \ldots\ldots\ldots\ldots\ldots\ldots \quad \text{(v.)}
\end{aligned}$$

Differentiating this last expression twice with regard to $\theta$, and putting $\theta = 0$ we find

$$\left(\frac{du}{dx}\right)_{\frac{1}{2}} = \Delta_1 - \frac{1}{24}\Delta_3 + \frac{3}{640}\Delta_5 - \frac{5}{7168}\Delta_7 + \ldots\ldots \quad \text{(vi.)}$$

$$\left(\frac{d^2u}{dx^2}\right)_{\frac{1}{2}} = \Delta_2 - \frac{5}{24}\Delta_4 + \frac{259}{5760}\Delta_6 - \frac{3229}{322560}\Delta_8 + \ldots\ldots \quad \text{(vii.)}$$

Thus for $y = 5{\cdot}25$, in the above example, we find

$$\frac{du}{dx} = 19057{\cdot}17,$$

the true value being

$$\frac{du}{dx} = 19056{\cdot}63.$$

(4) The ormula (iv.) is useıul for constructing tables by means of interpolation. For halving the intervals in a table, it gives

$$u_{\frac{1}{2}} = \mathrm{V} - \tfrac{1}{8}\Delta_2 + \frac{3}{128}\Delta_4 - \frac{5}{1024}\Delta_6 + \frac{35}{32768}\Delta_8 - \ldots \quad \text{(viii.)}$$

Similarly, for subdivision of the intervals into fifths,

$$\begin{aligned}
u_{\frac{1}{5}} = \mathrm{V} &- {\cdot}3\Delta_1 - {\cdot}08\Delta_2 + {\cdot}008\Delta_3 + {\cdot}0144\Delta_4 - {\cdot}000864\Delta_5 \\
&- {\cdot}0029568\Delta_6 + {\cdot}00012672\Delta_7 + {\cdot}00064204 8\Delta_8 - \ldots \\
u_{\frac{2}{5}} = \mathrm{V} &- {\cdot}1\Delta_1 - {\cdot}12\Delta_2 + {\cdot}004\Delta_3 + {\cdot}0224\Delta_4 - {\cdot}000448\Delta_5 \\
&- {\cdot}0046592\Delta_6 + {\cdot}00006656\Delta_7 + {\cdot}001018368\Delta_8 - \ldots \quad \text{(ix.)} \\
u_{\frac{3}{5}} = \mathrm{V} &+ {\cdot}1\Delta_1 - {\cdot}12\Delta_2 - {\cdot}004\Delta_3 + \text{\&c.} \\
u_{\frac{4}{5}} = \mathrm{V} &+ {\cdot}3\Delta_1 - {\cdot}08\Delta_2 - {\cdot}008\Delta_3 + \text{\&c.};
\end{aligned}$$

the terms in $u_{\frac{3}{5}}$ and $u_{\frac{4}{5}}$ being the same as in $u_{\frac{2}{5}}$ and $u_{\frac{1}{5}}$, but with signs alternately alike and different; and the sequence of signs in each case being . . . + + − − + + . . . The corresponding formulæ for subdivision into tenths might be found; but it is simpler to subdivide into halves and then again into fifths.

When several differences have to be taken into account, the above method of direct calculation is less troublesome than the ordinary process of building up the table by calculation of the sub-differences.

In the formulæ (ix.) the terms due to V and $\Delta_1$ have been given in the form $\mathrm{V} - {\cdot}3\Delta_1$, $\mathrm{V} - {\cdot}1\Delta_1$, . . . ; but in practice these terms would be obtained by successive additions of $\cdot 2\Delta$ to $u_0$, so that it is not necessary to calculate V.

## Apparent Dark Lightning Flashes.

ON the evening of the 5th of the present month we were visited by a severe thunderstorm, which passed practically over this place. The lightning was very vivid and at times occurred at intervals of only a few seconds. In order to photograph some of the flashes I placed a camera on my window sill and exposed four films for consecutive periods of 15 minutes each.

During the exposures I was observing the sky, and repeatedly found that after nearly each bright flash I could see distinctly a *reversed image* of each flash *in any part of the sky* to which I turned my head. These apparent dark flashes, or rather the images on my retina, lasted for sometimes 5 to 10 seconds. At the time I wondered whether dark flashes had ever been noticed before, and thought that this phenomenon was not uncommonly observed, but seeing Lord Kelvin's letter in your issue of August 10, I send this note in case it may prove of interest.

Westgate-on-Sea, August 13. WILLIAM J. S. LOCKYER.

## Subjective Impressions due to Retinal Fatigue.

IN reading the interesting optical experience as described by Lord Kelvin in NATURE of August 10, it occurred to me that a somewhat similar effect on the eye, as noticed by myself, might be of interest.

Frequently late in the evening, and with a dull cloudy sky, I have seen my own figure, at least in part, apparently projected in gigantic form high up on the cloudy background.

This happened in the following manner. Going to the door of the house, and standing there with the strong light from the lobby or hall lamp shining out upon the gravel-walk in front, I saw my figure in shadow strongly defined upon the illuminated pathway. On raising my eyes quickly to the sky, I there saw the same form marked out on the dark clouds, but in a lighter shade.

The effect on the eye, as in Lord Kelvin's experience, is doubtless that of fatigue: in my experience, however, the form observed being very dark as compared with the illuminated background, I received the complementary impression of a light-coloured figure on a dark background.

The time during which this impression remained when looking at the clouds might be a couple of seconds.

August 14. W. J. MILLAR.

## Mathematics of the Spinning-Top.

IT should have been stated on p. 321 that, while $\theta_3$ is the angle between HQ and HQ′ in Fig. 1, p. 347, the angle between HS and HS′ is $\theta_2$. At the same time this opportunity is available for some corrections, for which the printers are not responsible. On p. 321 the values of sin $\theta_3$ and sh $\theta_1$ should be interchanged; on p. 348, after equation (35), read ... "MX is the harmonic mean of MT, MT′ and of M*m*, M*m*′, ..."

## ON SPECTRUM SERIES.[1]

### II.

It is well that I should indicate the basis of these statements, and for this purpose I throw on the screen a very small part of the spectra of two or three different substances in order that you may see the way in which the work has been done. Take the lowest horizon. There we are dealing with zinc, and you see the way in which the triplets have been picked out. The triplet in each case, of course, supposing it is the remnant of a fluting, has its central line nearer to one side of the triplet than the other. All the triplets in the zinc spectrum are perfectly symmetrical from that point of view. If we take the upper spectrum—that of calcium—we find also that the triplets are formed in exactly the same way. We can quite understand the enormous labour which has been involved on the part of the inquirers I have named in working out from the spectra of a great many substances and from all the different regions of the spectrum, visible and photographic, these delicate triplets. In a great many cases they do not represent the strongest lines, those most easily seen, and they want a great deal of looking for.

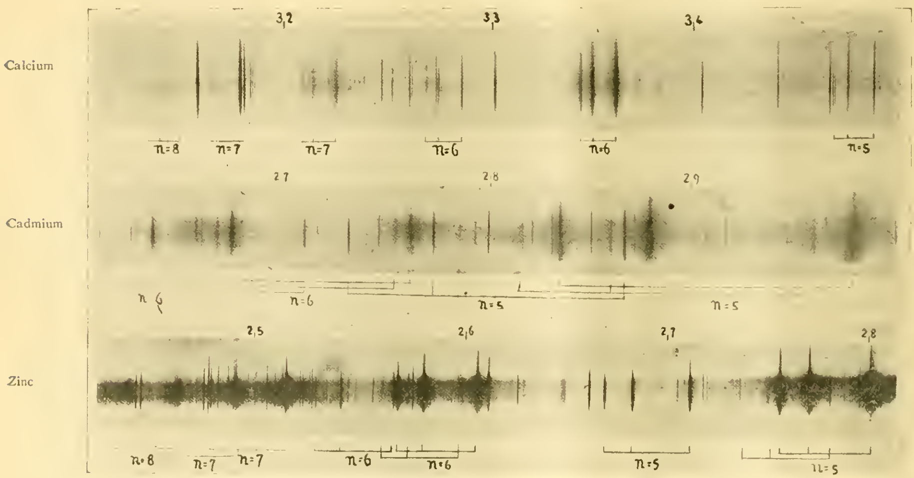

FIG. 6.—Parts of the spectra of calcium, cadmium and zinc showing the triplets.

I next pass on to some more general statements, which I am anxious to put before you for the reason that you will not find them stated in any literature that I am acquainted with; the subject has really not been generally discussed at all.

Some substances have three series, as in the case of helium and asterium. There are others like them; and the most remarkable case which I have to bring before you is that of hydrogen. We do not know the meaning of it yet, but it has to be taken into account in any consideration of these questions. Until a little time ago only one series was known in the spectrum of this gas, and it was thought that on that account the atom of hydrogen was far more simple than that of any other chemical elements. A short time ago, however, Prof. Pickering, in his magnificent work on the stars, to which I have already had the opportunity of referring, discovered a second series of lines. Not long after, Prof. Rydberg suggested that one of the most important lines seen in a large group of stars really represented a line of the principal series of hydrogen. That conclusion has been generally accepted, although the evidence is considered doubtful by some; so that we now assume that hydrogen has three series like helium and asterium, and we seem therefore to be on solid ground in one direction, at all events, in regard to some gases. We have another series of metals of low atomic weight, and which therefore chemically are supposed to represent a considerable simplicity; we find that in the case of lithium and sodium we also deal with three series, a principal series and two subordinate series. The series of lithium are just as beautiful in their rhythm as the other series to which I have referred. The same remark applies exactly to sodium. Now, it has recently been found that sulphur and selenium also give us three series. We have a principal series and the first and second subordinates, but the suggestion of anything beyond these three is confined to one or two lines in each case. Next let us take another gas, and see what happens in the case of oxygen. *We have six series*, that is twice as many as we know of in hydrogen, helium, asterium, lithium, sodium, sulphur, and so on. I should say that so far as that goes we are in the same condition that we were some time ago when we imagined that the gas obtained from the mineral cleveite was really a single gas with six series. Very many arguments have been employed to show that that view is probably not an accurate one; so that some are prepared to separate the cleveite gases at spark temperatures into two, calling one helium and the other asterium. That brings these two constituents of the cleveite gas then to the same platform as hydrogen with the recent developments, lithium, sodium, sulphur, &c. If we come to consider this extraordinary condition in the case of

[1] A Lecture to Working Men, delivered at the Museum of Practical Geology, on May 1, by Prof. Sir Norman Lockyer, K.C.B., F.R.S. (Continued from p. 370.)

oxygen a little further, we find that the six series only after all pick up the oxygen lines seen at a low temperature, and that if we employ a high temperature to observe the oxygen spectrum, that is to say, if we use an induction coil, a jar and an air break, we find a very considerable number of lines indeed which have no connection whatever with the series. And we are face to face with this very awkward fact, that in the case of oxygen there are more lines which we cannot get into a series than there are lines in the six series which we have attributed to that chemical substance. Here, therefore, we begin certainly to get into difficulties. The inquiry is not so straightforward, the conditions are not so constant, as we might have expected them to be.

Here then we have instead of three series twice that number, and these only account for about half the lines. Now, let us look still a little further. The next point is that in the case of other substances *we have no principal series*, but only two subordinate ones. This happens in the case of magnesium, calcium and strontium. We have only two series in the case of magnesium, two in calcium, and two in strontium. In all those three we have a first and second subordinate series, but no principal series. I have studied the lines of calcium and magnesium, in the same way that the lines of oxygen were studied to see how many of the lines are picked up by the series. In the upper part of the diagram we have the lines seen in the arc spectrum of calcium, and in the two next horizons we have the lines picked up in the first and second subordinate series. The next horizon gives the residual lines—lines, that is, which have not been distributed into any of these series. You see that there is a large number outstanding just as in the case of oxygen, and it is very important indeed to note that the two lines H and K, which are more conspicuous in the spectrum of the sun than all the other lines of the spectrum, have not been caught by any of these researchers into the series of calcium. Therefore, with a reduced number of series, we seem to be getting still further from the simplicity we began with in the case of some of the permanent gases like hydrogen and helium. The same thing holds with regard to magnesium, the spectrum of which at the temperature of the arc has not so many lines in it as the spectrum of calcium. A certain number of these lines has been picked up to form the series, but we get numerous lines which have been left over after all attempts to sort them into series have been made.

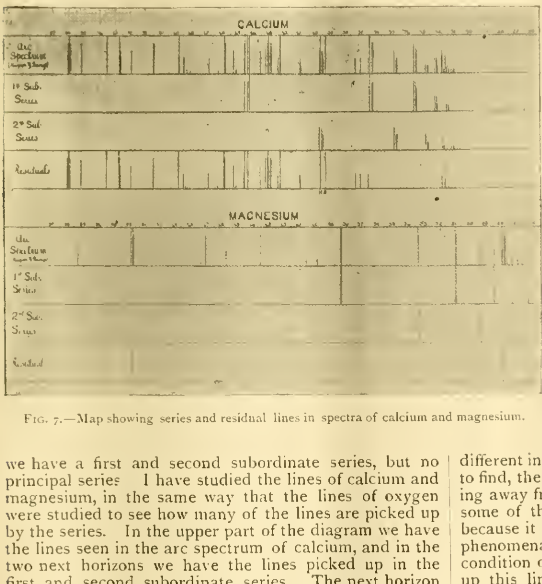

FIG. 7.—Map showing series and residual lines in spectra of calcium and magnesium.

I have now to bring before you another consideration. We are dealing in the case of calcium and magnesium with arc temperatures, but I showed you in my first lecture that in the case of calcium and magnesium the all-important lines in the hottest stars were lines seen at the temperature of the spark. I have added these lines to the diagram, and you will see that there is not the slightest trace of those lines having been picked up in the series. So that the further we go, the more we seem to get away from that beautiful simplicity with which we began. I take you now to another group of substances, namely, tin, lead, arsenic, antimony, bismuth and gold, and I might mention more. No series whatever have as yet rewarded the many attempts of those who have tried to get those metals and non-metals on all-fours with those previously investigated. It remained for Kayser and Runge to point out that it looked very much as if this complete absence of series was connected with the melting point of the substances with which they had been dealing. So long as the melting point was low, as in the case of sodium and lithium, the normal three series would show at low temperatures; and, further, there were no lines over. But, when you get to these substances with high melting points, there is no series at all, and of course it is suggested that therefore there must be intermediate stages; and that really seems to be a very valid suggestion indeed, and one which in all probability will enable us to get over some of the difficulties. They point out that in the case of lithium, sodium, potassium, &c., all the lines are picked up, and that in the case of copper, silver and gold the series pick up only a very small proportion. There seems, therefore, to be a progression of complexity with the increasing melting point with regard to all the metallic substances which have so far been examined; of course this consideration does not touch the question of oxygen. Oxygen is a gas, hydrogen is a gas in consequence, of course, of their very low melting points, and you know that quite recently it has been found possible to liquefy both of them. So that there must be something different in their case, and it seems extremely encouraging to find, therefore, that the same variation, the same breaking away from the law which I pointed out in the case of some of the metals, should really occur also in a gas, because it seems as if we shall be able to explain the phenomena in both cases by supposing that there is a condition of greater complexity, and that when we follow up this line of greater and greater complexity, whether in a gas such as oxygen, or in a solid such as gold, we do not get the simple series, because at the temperatures we employ we are still far from the simple condition which we can get at in some gases and in some metals with low melting points. The table gives the relation between the melting point and the percentage of lines sorted into series. Thus, in the case of barium with a high melting point we get no lines at all represented in the series; then we gradually get up to 100 per cent. in the case of lithium. But then again, as in the case of oxygen, when we come to mercury, which is also of low melting point, instead of getting 100 per cent. we only get about 25 per cent. of the lines represented in the series.

Relation of series to melting points.

| Element | Melting point | Percentage of series lines |
|---|---|---|
| Barium ... ... | 1600° | 0 |
| Gold ... ... | 1200 | 4 |
| Copper ... ... | 1050 | 6 |
| Silver ... ... | 960 | 26 |
| Strontium ... | 700 | 20 |
| Calcium... ... | 700 | 34 |
| Magnesium ... | 600 | 64 |
| Zinc ... ... | 410 | 80 |
| Cadmium ... | 320 | 50 |
| Lithium... ... | 180 | 100 |
| Sodium ... ... | 90 | 100 |
| Cæsium... ... | 62 | 100 |
| Potassium ... | 58 | 100 |
| Rubidium ... | 38 | 100 |
| Mercury... ... | – 40 | 27 |

These matters, of course, have been very carefully inquired into, and among them I will just point out that Meyer has shown that if the wave-lengths of all the lines for $n = \infty$ be calculated and put as ordinates, and the atomic weights as abscissæ, then all the points lie on a curve similar to that which gives the atomic volumes as functions of the atomic weights. He not only deals with the melting points, but he goes further and attempts to associate the melting points with the atomic weights.

The next consideration is that in these investigations, in some cases, the series have reproduced the same chemical group, but in some instances the series groupings, so to speak, are quite different from the chemical groupings.

The facts so far ascertained are as follows:—

Group 1 ... Lithium, Sodium, Potassium, Rubidium, Cæsium.
,, 2 ... Copper, Silver, (Gold ?).
,, 3 ... Magnesium, Calcium, Strontium.
,, 4 ... Zinc, Cadmium, Mercury.
,, 5 ... Aluminium, Indium, Thallium.

In the group of lithium, sodium, potassium, the series sequence follows absolutely the chemical sequence. But when we come to the chemical group—calcium, strontium, barium—you find it replaced by a group, magnesium, calcium, strontium, while barium is not used at all. That is a very remarkable departure, and it shows that we have to consider the various conditions which we observe in passing from group to group.

From *group* to *group* with increasing atomic weights the series back towards the violet. Thus, as the limit of a series is represented by the first constant for the first subordinate of the four groups, the limit lies

Between 2858·6 and 1974·3 for Lithium, Sodium, Potassium, Rubidium, Cæsium.
,, 3159·1 ,, 3078·2 ,, Copper, Silver, Gold.
,, 3979·6 ,, 3103·0 ,, Magnesium, Calcium, Strontium.
,, 4294·5 ,, 4015·9 ,, Zinc, Cadmium, Mercury.

In *each group* with the increasing atomic weight the spectrum advances continually towards the red end; that is, in exactly the opposite direction we observed before.

Having dealt with these details, there are several other general questions which I should like to say a word about, because it is evident that we are here in presence of the beginning of a new attack on the nature of the chemical elements.

Let us attempt to compare these simplest results obtained by this newest form of spectrum analysis, in other words the simplest series, with the earliest stellar forms.

We found that the hottest stars contained hydrogen, helium, and asterium. Well, we have found that those substances have the simplest series; that is to say, one set of three. I told you that it was more than probable, although it is not absolutely established, that the lithium group of metals is also represented in stars of very high temperature. There, again, we have the simple series of one set of three. About sulphur we do not yet know positively, but it is probable, I think, that sulphur may exist in the hot stars. There, again, we get another simple set of three; so that for three perfectly certain members of the hottest stars, together with one in all probability and one doubtful, we are dealing with the simplest series in the hottest stars.

But now comes the remarkable fact that side by side with these simple substances we get in the hottest stars magnesium and calcium. We cannot suppose that the absence of the principal series there means a greater simplicity, because I have shown you that only about half the lines in the spectrum of each of these substances has yet been picked up in the series, and if the series represent the vibrations of a single particle, of course the lines which are not represented in the series, by theory must represent the vibrations of some other particles. So that there we are face to face with the possibility of a much greater complexity. Coming a little further down in stellar temperatures we find oxygen, and here we deal with six series instead of three, or two, as in the case of magnesium and calcium; and even then, as I have pointed out to you, we do not deal with above half the lines of the gas as we can see them at a higher temperature. This, then, seems to suggest that in the hottest stars there are very various stabilities of very various forms. In fact, there seems to be there as here distinctly the survival of the fittest; otherwise how can we account for the fact that certainly in the hottest stars we get two metals, magnesium and calcium, before we have indication of any other metals, and that where we have those metals and bring our series touch-stone to them we find that instead of being very simple they are really very complex? However this may be, we are now assured that there is a much greater quantity of some apparently more complex forms in the hotter stars than of the more simple ones; and that is a matter which the chemists, when they come to inquire into these questions which we are now considering, will certainly have to face. This fact suggests, too, another very interesting question which has some relation, perhaps, to some of those drawings that I have thrown on the screen from Lyell's Elements, which showed that a great many simple organic forms appear in the stratigraphic series at a late period; that some of the simplest forms died out, others remained. Now, it may be that some of the more simple forms in inorganic evolution, as in organic evolution, really represent later introductions; but, however this may be, it is perfectly certain that we have not an absolute parallel between the results of the spectroscopic observations of series and the spectroscopic observations of stars. The accompanying table will show very generally how the matter stands. The chief points to refer to are the gaps in the table showing the principal series and the first and second subordinate series. We have the metals arranged in the order of Mendeléjeff's groups. You will observe that after the first metals we practically deal with no principal series at all until we come down at the bottom to oxygen, sulphur and selenium. The same thing happens with the subordinate series so far as the existence of single lines and double lines are concerned. Now, it is a curious point that in the case of several of those substances in which no principal series has been detected, certain lines in the ultra-violet of considerable strength have been observed which may ultimately turn out to represent principal series. Of course, if that should be so it will make the inquiry a

very much simpler one than it appears to be at present, and it may possibly break down that terrible amount of uncertainty and irregularity which it has been my duty to point out to you in the series so far examined.

there is no fluting from one end of the spectrum to the other..

Rydberg has suggested that an investigation of the so-called "longest-lines" of the various substances may

| | Mendff. groups. | Atomic weights. | No. of series. | No. of principal series. | Principal series. Single. | Principal series. Double. | Principal series. Triplets. | 1st and 2nd subordinate. Another matter of considerable importance to us in attempting to arrange the chemical elements along this line of series—and it is work that is sure to be done now that the matter is started—is to endeavour to see if there is any strict relation between those chemical substances which give us these simple series and those which are more apt to provide us with those exquisite rhythmic flutings. In some of the elements the flutings and the proportions of them from one end of the spectrum to the other are very remarkable, but in other metals the wonderful thing about them is that practically

eventually help us in our inquiries. I will tell you what the longest-line means. If we examine a light source by pointing the spectroscope directly at it, of course the rays from every part of the light source enter the instrument; but if we throw an image of the light source on the slit of the spectroscope, then those particles which exist furthest from the centre will be visible furthest from the image of the centre, and therefore if they are visible enough to give spectra, we should get long lines stretching from the centre to the very limit at which their light is visible enough to be utilised by the instrument. As a

matter of fact we do see some very long lines in this way in the case of some substances, and these of course appear to be quite distinct from the shorter lines which are limited to the exact centre of the spark or the arc; to the region, that is, in which the very highest temperature is at work. Rydberg has shown that in a considerable number of cases long lines seem to have a very considerable importance, and on that account it is well worth inquiring into. Rydberg's investigations of the members of the first three groups of the periodic system led him to conclude that the long lines form pairs or triplets, which in the case of each element are characterised by a constant difference ($v$) in the number of waves of the components. For each group of elements shown in Mendeléjeff's table, this value he finds increases in a ratio somewhat exceeding the *square* of the atomic weight.

What, then, is the general result ot our inquiry, taking series in inorganic evolution to represent the cells which are microscopically studied in the case of organic evolution? I think you will agree that the evidence is that, however simple the organic cell may be, the chemical units in the case of any substance represented to us by the movements which are written out by these series must possess different degrees of complexity. I have already told you that a little time ago it was imagined that hydrogen was rendered visible to us by such simple vibrations that only one series of lines could be produced. If that is so, then it looks very much as if whenever we see three series of lines that three molecules or atoms, three different things, are in all probability at work in producing them. When we get six series, that points to a still greater complexity, and when as in the case of oxygen we get six series not accounting for half the lines, then we should be quite justified, I think, in supposing that oxygen was one of the most complex things that we were brought face to face with in our studies of series. When we come to metals where there are no series at all, what do we find? We find that we are dealing with substances with high melting points—that is to say, we cannot bring them down easily to those mobile states represented by the free paths of a permanent gas; and it is quite easy to suppose, on that account alone, that we do not see the vibrations of any of the more simple forms. Therefore, I think it is perfectly certain that we have not universally got down to the equivalent of the cell-level in our study of chemical forms.

With regard to this question of the relation of the two evolutions inorganic and organic, I have still one more diagram which will give an idea of the place of organic evolution in regard to inorganic evolution in the scale of time. I do not want you to pay too much attention to this diagram, because it is entirely hypothetical; but it is constructed on the simplest principles, so that it shall go as little wrong as may be. I begin by drawing a line at the bottom, which represents the zero of temperature; certain temperature values are indicated on the left-hand side of the diagram. Then we have the assumption that a star loses an equal amount of heat in an equal period of time. In that way, then, you see at the bottom we have relative times, as at the side we have temperatures, in Centigrade degrees. Water freezes at a certain temperature above absolute zero, and boils at a certain other point; these are marked on our temperature scale. Then we have to remember that about half-way between the boiling point and the freezing point, all the organic life with which we are familiar on this planet, from the geological evidence and our own experience, must have gone on at a temperature of somewhere about, let us say, from 50° to 40° Centigrade. There, then, we get the limit of organic life in relation to the possible inorganic life, represented by the various chemical changes in the stars. We know from laboratory statements that the stars of lowest temperature are about the same temperature as that of the electric arc, which is about 3500° C., and so we put the Piscian stars there. It has also been stated by Mr. Wilson lately that the temperature of the sun measured by several physical methods is something between 8000° and 9000° C., so that we put there the Arcturian stars. Of course we have no means of determining the temperatures of the hotter stars, so I have ventured to make a very modest supposition that possibly we get about half the difference of temperature between those stars as we have found between the Piscian and the Arcturian stars from experiments on the earth. That will give us roughly something like 5000° C. We find then that if we assume equal increments of temperature for each of the different genera of stars that I brought before you in the second lecture, we get a temperature at the top of the diagram of something like 28,000° Centigrade. All we have to do, then, is to draw a diagonal line on which to mark the various temperatures considered. On this the organic evolution, which represents everything which has taken place with regard to living forms on the surface of our planet from the pre-Laurentian times to our own, is represented by a small dot. It looks, therefore, very much as if these recent results of spectrum analysis, which it has been my duty and my pleasure to bring before you in this course of lectures, may probably be of some value in the future, because they deal with a multitude of changes and a period of time compared with which all the changes discussed by the geologists are almost invisible on a diagram of this size. Not only shall we have probably some help in determining this scale, but I think that, as I have already indicated to you, the wonderful similarity between the substances contained in the organic cell and those which would most likely be free when the greatest amount of chemical combination had taken place on the surface of the cooling world, will throw some light on the basis of organic evolution itself.

In that way, then, we have really been only continuing courses of lectures given here formerly, which had to do with Man's Place in Nature, and with the Sun's Place in Nature; and I think you will agree that we have found fresh grounds for thinking that the more different branches of science are studied and allowed to react on each other, the more the oneness of Nature impresses itself upon the mind.

## *NOTE ON THE DISCOVERY OF* MIOLANIA *AND OF* GLOSSOTHERIUM (NEOMYLODON) *IN PATAGONIA.*[1]

SINCE 1877, when I discovered the Tertiary Mammalian beds of Santa Cruz, in Patagonia, I have been looking for proofs of the ancient connection between the new uplifted lands of the southern part of the American continent and the other lands of the Southern Hemisphere—Africa and Australia. During my subsequent travels in the interior of the Argentine Republic, including Patagonia, my interest in that connection has been increasing, and I have discovered additional evidence, which showed me the former greater extension to the east, in comparatively modern times, of the actual existing lands. The splendid results of the researches made by the La Plata Museum in Patagonia have revealed a greater number of lower forms of vertebrates, including numerous marsupialia, some of which seem to me closely related to the mammals of the Pleistocene fauna of Australia, and among them *Pyrotherium* and *Diprotodon*. I think that my suggestion has an indubit-

[1] By Dr. Francesco P. Moreno, Director of the La Plata Museum. (This article will appear in the *Geological Magazine* for September 1, and is printed in advance in NATURE, by permission of Dr. H. Woodward, F.R.S.)

able confirmation in the discovery made by the expeditions which I sent in 1897 and in the first months of this year, under the direction of Mr. Santiago Roth, expeditions that have had astonishing results.

In beds containing remains of mammals and dinosaurians, Mr. Roth discovered in 1897 a caudal sheath-ring, very similar to those of the *Glyptodon*, but which I at once recognised as pertaining to a form like the chelonian of the Pleistocene of Queensland, described by Owen. I brought this fossil with me to London for comparison with the remains of *Miolania* preserved in the British Museum (Natural History). The resemblance was great, but the fact of a Tertiary chelonian from

B. A.

FIG. 1.—A, front view of skull; and B, side view of tail-sheath, of *Miolania Oweni* (greatly reduced in size) from Pleistocene deposits, Queensland, Australia [originally described as *Megalania prisca* by Owen in 1880].

Patagonia being analogous to the Pleistocene genus from Queensland and Lord Howe Island was so astonishing that some doubt was permitted; but, having previously ordered a new examination of the fossiliferous bed where the remains were found, I have now the certainty of the extremely close relation between the Australian and Patagonian chelonian. I have received several photographs of a skull discovered by Mr. Roth, which photographs, when compared with the Australian specimens in the British Museum (Natural History), give no place for doubt upon this matter. I think that it is sufficient for the present to give two cuts representing the two forms of *Miolania*. I expect in a few days the original specimen from Patagonia, together with various bones and additional remains of the caudal sheath, with some of the carapace. These will be the subject of a special description by Mr. Arthur Smith Woodward, who has so kindly commenced studies on the fossil reptiles in the La Plata Museum.

I have also brought with me to London a piece of a skin discovered in a cave near Last Hope Inlet (lat. S. 51° 30′), which I have referred to a species of the extinct *Mylodon* (see "On a Portion of Mammalian Skin, named *Neomylodon listai*, from a Cavern near Consuelo Cove, Last Hope Inlet, Patagonia," by Dr. F. P. Moreno; with a description of the specimen by A. Smith Woodward); while Mr. Ameghino has announced that another piece of the same skin pertains to a mammal still living, of small size, which he has called *Neomylodon*. When I took this piece at Last Hope Inlet in November 1898, I was convinced that it was part of the skin of a *Mylodon* or a form very similar to it, and that the discovery was of great importance to me, as I think that the Pampean muds, where the extinct Edentata are found, are of very modern age; an opinion contrary to that held by another observer, Mr. Ameghino, who refers the Pampean fauna to the Tertiary age. I have already maintained that the extinction of the greater part of the Pampean fauna took place after the presence of man in a relatively advanced culture, called Neolithic culture. Having, then, great interest in the continuation of the investigations in the cave, I ordered, before coming to London, more extensive researches, and these have been made with very successful results.

Dr. Otto Nordenskjöld had previously obtained in 1896 a piece of the same skin, which, it is known, was discovered by a party of Argentine surveyors during the preliminary studies for the boundary between Argentina and Chili in the Andean Cordillera, and, recognising also the importance of it, Dr. Erland Nordenskjöld went last year to the same spot to look for some more remains. The excavations which he made gave him, so far as I know, some bones, pieces of jaws, teeth, and claws of the same animal, but he did not obtain more remains of the skin.[1] My assistant, Mr. Hauthal, arrived later at the cave, when Dr. Erland Nordenskjöld had terminated his researches and commenced further exploration. He obtained, not only skulls, jaws, teeth, bones and claws, but also a nearly complete skin of the animal, which shows that it is a *Glossotherium*, together with bones of *Macrauchenia*, *Equus*, and *Auchenia*, also a great quantity of dung, hay cut by man, ashes, and some bones worked by man. I am not yet sure if the bones of man discovered by Mr. Hauthal were found in the same cave or in one of those in its neighbourhood; but the presence in the *Glossotherium* deposit of bones worked by man is a proof that man and other mammals, whose remains have been discovered in the cave, were contemporary. I suggest that the skin has been preserved by man for bedding. In the caves inhabited by ancient man in Patagonia I have seen cut hay, and probably this also was used for beds.

I expect to receive in a few days all these specimens at the same time as those of the *Miolania*, together with reports on the discoveries, and I think they will arrive in time for me to exhibit these remains at the meeting of the British Association at Dover.

The discovery made by Mr. Roth of some advanced Mammalia in the beds that contain dinosaurians, and Mr. Hauthal's discovery of remains of extinct vertebrates and other mammals in the caves of Southern Patagonia, associated with *Macrauchenia*, *Equus*, *Auchenia*, and man, are proofs of the very recent changes in the physical geography of Patagonia, and afford most

FIG. 2.—Reproduction of a photograph of the front view of skull, with the lower jaw, of *Miolania*, obtained in 1899, from Patagonia, by Mr. Santiago Roth, of the La Plata Museum, Argentine Republic (greatly reduced in size).

interesting problems, which can only be solved by a systematic examination of the Argentine country by experienced geologists. In the course of my paper on Patagonia, read before the Royal Geographical Society (May 29), I proposed that this Society, the Royal Society, and the British Museum, with other scientific institutions, should proceed to carry out these necessary investigations. These problems are not extraneous to the explorations which may be carried out by an Antarctic

[1] "E. Nordenskjöld, Neue Untersuchungen über *Neomylodon listai*, Zool. Anzeiger," vol. xxii. (1899) pp. 335–336.

expedition, and I think the new discoveries which I now communicate to the *Geological Magazine* may urge on the despatch of such expeditions as I propose. If these expeditions be made, how many changes may be produced in actual and general ideas on the age of the South American fossiliferous strata, on the disappearance of the lost southern lands, and on the affinities of extinct faunas so distant in time and space as those of South America and Australia!

## *MR. JOHN CORDEAUX.*

BY the death of Mr. John Cordeaux, ornithology loses, not only one of its most ardent votaries, but one who had pursued, if he did not strike out for himself, a line very different from that taken by most British lovers of birds. For nearly six-and-thirty years, as shown by a long series of contributions, chiefly to *The Zoologist*, he applied himself to the study of the phenomena of bird-migration, at first as exhibited on the coasts of Lincolnshire (in which county he lived) and Yorkshire. This led him in the autumn of 1874 to go to Heligoland for the sake of comparing notes with the now well-known Herr Gätke, whom, it is believed, he was the first British ornithologist to visit; and he soon after wrote for *The Ibis* (1875, pp. 172-188) a notice of the very wonderful collection formed by that naturalist on that island. In 1879 he joined Mr. Harvie-Brown (who had just communicated a remarkable paper to the Natural History Society of Glasgow) in a successful attempt to procure observations on migrating birds from the keepers of lighthouses and lightships on the coasts of England and Scotland; and in the following year, when the results of their inquiry were brought before the British Association at the Swansea meeting, he was named secretary of a committee appointed to continue systematically the scheme which they had shown to be practicable. Of this committee, which (with a slight variation of title) has since been annually reappointed, he has always been the hardworking secretary, and it is not too much to say that nearly all its success is mainly due to him. He not only arranged with the authorities for the distribution of the schedules, instructions, and other information necessary for the observers, but, by his own efforts, raised by subscription a large sum of money to meet the expenses of the inquiry, which proved to be far greater than had originally been anticipated. The time and trouble which all this involved were at first enormous; and, even to the last, the correspondence which he had to carry on was immense, yet his services were as willingly rendered as though he had been handsomely paid for them, instead of giving them gratuitously, and the way in which he contrived to interest the men at the lighthouses and lightships in the undertaking was marvellous. The results of this labour, continued without intermission for nine years, were partly shown by the admirable "Digest of the Observations," made by Mr. W. Eagle Clarke, which the committee was able to include in its report presented to the Association at Liverpool in 1896; and, as has been announced, that gentleman is still occupied in working out further details from the mass of materials that has been collected.

Mr. Cordeaux made more than one visit to Heligoland, and is understood to have been instrumental in bringing about the publication of an English translation of Gätke's celebrated work, though never committing himself to the adoption of his friend's views on many points. Indeed, he abstained on principle as much as possible from advocating any theories on the subject of migration, being convinced that much more knowledge had to be acquired from observation before more than a few first principles could be safely accepted. That he was the life and soul of the Migration Committee is beyond all doubt. His happy tact and sanguine temperament overcame all difficulties, though—especially from the financial point of view—they were at times so formidable as to threaten the abandonment of the work; yet by his care funds were always found to carry it on, eking out the successive and by no means illiberal grants of the British Association. He is said to have been very successful as a lecturer, and he often lectured on some ornithological subject, especially on the migration of birds, in the towns of Yorkshire and other parts of the country.

Forty papers are credited to Mr. Cordeaux in the Royal Society's Catalogue up to 1883, a number which might possibly be doubled now, and in addition to these he was the author of an unassuming but well-written little book, "Birds of the Humber District," published in 1872, a new edition of which it had been his intention to bring out. He died, after a short illness, at his residence, Great Cotes House, in Lincolnshire, on August 1, in the sixty-ninth year of his age, deeply lamented by all who had been associated with him in the work he so indefatigably carried out.

A. N.

## *NOTES.*

WE much regret to record that the serious illness of Prof. R. W. Bunsen, referred to in last week's NATURE, has ended fatally. An account of the chief work of this world-renowned chemist appeared nearly twenty years ago in our Series of Science Worthies (vol. xxiii.), and we hope to publish a further appreciation of the deceased investigator next week.

THE funeral of Sir Edward Frankland took place at Reigate on Tuesday. There were present, in addition to the immediate relatives, Sir Frederick Bramwell, Lord Lister, Sir Henry Roscoe, Sir Myles Fenton, Sir Michael Foster, Dr. Ludwig Mond, Dr. Thorpe, and others. The Rev. Prof. Bonney conducted the funeral service. Many wreaths adorned the coffin, including one from the Fellows of the Institute of Chemistry and one from the Chemical Society.

MAJOR RONALD ROSS, the leader of the expedition sent to Sierra Leone by the Liverpool School of Tropical Diseases to investigate the possibility of exterminating the malaria-bearing mosquito, has sent to Liverpool the following cablegram: "Malarial mosquito found. Ask Government to send at once men." Major Ross's observations in India indicated that the malaria parasite is borne by the spotted-winged mosquitoes, and not by the common brindled or grey mosquitoes; and his message announces that he has found that malaria on the West Coast of Africa is produced under the same conditions as in India. There is evidence that the malaria-bearing species only breeds in small isolated collections of water which can be easily dissipated, but the expedition has not yet had time to verify this point.

THE presence of bubonic plague in Portugal has been officially notified to the Local Government Board. Oporto has been declared to be infected, and the other ports of Portugal are considered suspected. Port sanitary authorities in this country have been instructed in the precautions to be observed to prevent the introduction or spread of the disease here.

IT is announced that Sir Edmund Antrobus is desirous of selling Stonehenge, the famous and mysterious monument on Salisbury Plain. Thinking it right that the nation should have the opportunity of purchasing this great relic of antiquity, the owner has offered it to the Government, with about 1300 acres of surrounding land (subject to certain pasturage and sporting rights), for the sum of 125,000*l.*

Prof. George Forbes, F.R.S., has just visited the Niagara Falls Company, and he describes in the *Times* the remarkable success which the Company has attained in the use of the Falls to develop electric energy. An enormous number of factories has been established on the Company's land, and they use between them no less than 34,590 horse-power. Additions are to be made in October, and two new works, the Atchison Graphite Company and the Lead Reduction Company (Litharge), will be supplied, bringing the total up to 45,190 horse-power contracted for, with an income of over 150,000*l.* The operating expenses do not exceed 25,000*l.* per annum. The result indicates, among other matters, the strides which have been taken of late years in electro-chemical and metallurgical processes. With regard to the machinery, the dynamos, which were totally new, not only in size but in their general design, never give the slightest trouble; and the transformers, ranging up to 2500 horse-power, have answered their purpose perfectly, even with the low trequency of alternations, which was generally condemned when Prof. Forbes introduced it, but is recognised now by every one at Niagara as contributing largely to the success of the scheme.

The Wellman Polar expedition, which left Tromsö, Norway, on June 26, 1898, returned there from Franz Josef Land on August 17, on the s.s. *Capella*, which took the party on board at Cape Tegetthof. Mr. Walter Wellman's intention was to make a rush to the North Pole. According to the Reuter telegram received on Saturday last, an outpost was established as far north as latitude 81°, and two men were left in it to spend the winter, while the main party returned to Cape Tegetthof (lat. 80°). In the middle of February last, in the depth of winter, Mr. Wellman, with three Norwegians and forty-five dogs, started northwards. On reaching the outpost the two men were found, but one had been dead for two months. Pushing northwards the party discovered land north of the Freeden Islands, where Nansen landed in 1895. In the middle of March, when all hands were confident of reaching latitude 87° or 88°, if not the Pole itself, Mr. Wellman, while leading the party, fell into a snow-covered crevasse, seriously injuring his leg, and the party was therefore compelled to retreat. Two days later they were roused at midnight by an earthquake, and in a few moments many dogs were crushed and sledges destroyed. Mr. Wellman's condition became alarming on account of inflammation, but his companions dragged him on a sledge, making forced marches for nearly 200 miles to the headquarters of the expedition, where they arrived early in April. The *Capella* arrived at Cape Tegetthof on July 27, and sailed homeward with the party on August 10. Though the expedition has thus ended in failure so far as reaching the North Pole is concerned, it is stated that important scientific observations have been made by Dr. Hoffmann (naturalist), Mr. Harlan (physicist), and Mr. W. B. Baldwin, of the U.S. Weather Bureau, who accompanied the expedition as meteorologist and second in command.

Prof. Balbiani has just died at Meudon at the age of seventy-five years. The following particulars of his career are given in the *Lancet:* As Professor of Comparative Embryology at the College of France he was formerly assistant to Claude Bernard at the Museum. Although descended from an Italian family he was born at Havana, and pursued his medical studies at Frankfort-on-the-Main before going to Paris. His reputation was world-wide, and he leaves a considerable number of works, of which the best known deal with the constitution of the egg, the embryonic vesicle, cellular division, the reproductive process in infusoria and aphides, and silkworm disease. He had been many times a laureate of the Institute, but, despite most pressing invitations on all hands, he never presented himself as a candidate at the Institute or Academy of Medicine where he would certainly have been elected. He wished only to be a member of the Society of Biology, of which he was one of the oldest and most industrious members. Besides, for many years past he did not himself lecture, but devoted his time more and more exclusively to the laboratory, leaving his lecture work to his assistant, Dr. Hennegy. Prof. Balbiani was, with Prof. Ranvier, editor of the *Archives d'Anatomie Microscopique.*

The *Times* correspondent at St. Petersburg announces that a new regulation on Russian weights and measures was officially published on August 18. The Russian pound is fixed as the standard of mass and declared to be equal to 409·512 grams, a pail or vedro is to hold 30 pounds of distilled water at 16°·6 C., and a garnietz 8 pounds of water. The unit of length is the arshin, equal to 71·12 centimetres. The metric system is to be optional, and may be used with the Russian in commerce in dealing with contracts, accounts, &c., and after mutual agreement by State and municipal authorities. Private persons are, however, to be under no compulsion to use the metric system when dealing with the above-named authorities.

The *Scientific American* states that the creation of a great national forestry and game preserve in northern Minnesota, embracing 7,000,000 acres around the headwaters of the Mississippi River, with many lakes of rare beauty, well stocked with fish, will be advocated before the U.S. Congress next winter by prominent citizens of Chicago and Minnesota. It is believed that the promoters of the plan will not experience much difficulty in interesting Congress. The game and the virgin forests of the United States are disappearing so rapidly that it is exceedingly important that measures be taken, before it is too late, to save some of the great wooded areas of the continent.

Under the auspices of the Philadelphia Commercial Museum and the Franklin Institute, a National Export Exposition for the advancement of American manufactures and the extension of the export trade will be held from September 14 to November 30. At the end of last year the U.S. Congress voted 350,000 dollars in support of the exposition, and other funds, amounting to 100,000 dollars, have been provided by the City Councils of Philadelphia and private subscriptions. The exposition grounds comprise a tract of land, fifty-six acres in extent, granted to the Philadelphia museums by the city of Philadelphia, and another tract of six acres secured for the uses of the exposition. Of the five structures comprising the main exhibition buildings three are permanent, but will only be completed at the present time sufficiently for the purposes of the exposition. These three permanent pavilions will have two stories. They will each be 380 feet long and 90 feet wide. The space between them will be covered by temporary buildings connected with the pavilions, the whole forming a single harmonious edifice. The permanent buildings will eventually become the home of the Philadelphia museums. One of the chief events to take place in connection with the exposition will be the International Industrial and Commercial Congress, which will assemble in Philadelpnia, beginning on October 10. A number of foreign Governments have accepted the invitation to send official envoys, and almost every city of the United States and Canada with a population over 10,000 will be represented by delegates from their Boards of Trade, Chambers of Commerce, &c. Of special interest to the members of the Franklin Institute will be the ceremonies in commemoration of the seventy-fifth anniversary of the Society, which will be held in one of the exposition buildings. The arrangements for this event contemplate a series of commemorative meetings,

beginning Monday evening, October 2, and occupying the entire week. The evenings of the week will be occupied successively by the Sections in the order of seniority, beginning with the Chemical Section.

A SERIES of six articles "by a Contributor," which appeared in the *Banffshire Journal*, has been reprinted as a pamphlet entitled "Prof. McIntosh on Trawling and Trawling Investigations: a criticism and analysis." It is written with evident detailed knowledge of the work of the Scottish Fishery Board, and of fishery matters in general. Prof. McIntosh's tables and statistics are carefully analysed—the object being to show that the conclusions in his book, "The Resources of the Sea," are invalidated by the errors which have crept in in the transcribing and re-arranging of an enormous mass of figures from the Annual Reports of the Fishery Board. The matter in dispute is of such importance that the Fishery Board for Scotland in their next report should definitely and authoritatively state whether or not they accept Prof. McIntosh's statements as to the results of the trawling experiments off the Scottish coast, and, if not, what grounds they have for arriving at a different conclusion.

THE Meteorological Council have published a valuable contribution to maritime meteorology, viz. Meteorological Charts of the Southern Ocean between the Cape of Good Hope and New Zealand. The region embraces latitude 30° to 60° S. and longitude 10° to 180° E., and the charts show, for each month of the year, the wind direction and force for areas of 3° of latitude by 10° of longitude, the barometrical pressure by isobars, temperature of air and sea by isotherms, and ocean currents, in addition to other useful data. The publication will add considerably to the information hitherto available for this part of the ocean, and will therefore be very serviceable to navigators. Introductory remarks draw attention to all the leading results shown by the charts, and to the broad features of the distribution of barometric systems and of air and sea temperature. In the preparation of this work, observations for each four hours have been extracted from about 2450 logs kept for the Meteorological Office or on board H.M. ships, being all that were available between the years 1855 and 1895, and also from numerous logs of private shipping companies.

"SYMONS's British Rainfall" (Stanford) for 1898 contains not only the usual statistics and conclusions referring to the distribution of rain over the British Isles last year, but also several articles of general meteorological interest. Thirty-five self-recording rain gauges have been described in previous volumes, and eight more are described in the present report, several of them being illustrated by diagrams showing the principles of construction. In an interesting note Mr. Symons tests the general proposition that the annual rainfall increases with the elevation of the locality above the sea, by applying it to the English lake district. The highest station considered was at Sca Fell Pike (3200 feet), and the lowest Greenside Mine (1000 feet). Grouping the stations according to altitude in zones differing by 500 feet, no sign of increase or decrease of rainfall with altitude was found—in fact, the lowest group (1000–1499 feet) and the highest (3000 upwards) had identical annual precipitations, viz. 99·3 inches. Moreover, the rainfall at twenty-nine stations having annual amounts of 100 inches or more were arranged according to precipitation, but little evidence was afforded of an increase with elevation, and many of the results point to a conflicting conclusion. For instance, Seathwaite (altitude 422 feet) has an annual rainfall of 135 inches, while at Seatoller Common (2000 feet) the fall is 126 inches; Dungeon Gill and Ullscarf have both the same fall, though the altitude of the former is 311 feet, while that of the latter is 2100 feet. Mr. Symons concludes: "All these cases show that altitude alone has little influence on the amount of rainfall, and that in a mountainous country attention should chiefly be directed to the trend of the hills and valleys in relation to the rain-bearing winds."

DR. HERGESELL, of Strassburg, has contributed to the *Illustrated Aeronautical Magazine* (No. 4, *Jahrgang* 1899) a mathematical investigation of the theoretical vertical movements of a free balloon. The subject engaged the attention of Mr. J. Glaisher in the *Encyclopaedia Britannica*, and is of considerable interest for scientific balloon navigation. The first case considered is that of the ascent of an imperfectly inflated balloon, and the formulæ give the velocity attained in a stratum of air of a definite density, *i.e.* at a definite altitude, and the time required in reaching this stratum. In the case of a perfectly inflated balloon, the investigation shows that the maximum height that can be attained depends entirely upon the lifting power, and that it is independent of the velocity of ascent, and of the resistance of the air. In the case of the descent of a balloon, it is shown that the velocity of the fall does not continually increase, as is often stated, but, on the contrary, decreases, and that there is no danger in allowing the balloon to descend from a great altitude without throwing out ballast, as the velocity of the descent decreases according to the greater height from which the descent is made.

M. J. LIPPMANN, writing in the *Journal de Physique* for August, proposes the adoption of an absolute measure of time based on the Newtonian constant of gravitation. The possibility of establishing such a unit depends on the property that the Newtonian constant is independent of the units of length and mass, and is of minus two dimensions in time; hence, by making the constant of gravitation equal to unity, an absolute unit of time is obtained which is found to be equal to 3862 seconds of mean time approximately. The afore-mentioned property, however, involves the assumption that the unit of mass is of the same dimensions as the unit of volume; in other words, that density is of no dimensions. Strictly speaking, M. Lippmann's time unit is of $-\frac{1}{2}$ dimensions in density, and therefore its value depends on the nature of the standard substance chosen as the unit of density. The proposal practically amounts to this: instead of adopting an astronomical unit of density (corresponding to the astronomical unit of mass) based on taking the mean solar second as unit of time, we are to adopt an absolute unit of time based on taking water as the unit of density.

THE *Atti dei Lincei* contains in recent numbers two somewhat closely allied papers on thermo-electricity. The first of these is a verification of the principle of thermodynamic equivalence for bimetallic conductors, by Signor Paolo Straneo, who concludes not only that thermo-electric phenomena proceed regularly in perfect accordance with theory, but that they can be studied with sufficient exactness by temperature-observations without having recourse to calorimetry. The determination of the Peltier-effect coefficient by the author's method succeeds even in the case in which previous methods are wanting in accuracy, namely, when the two metals possess a high specific resistance and a feeble Peltier-effect. With the present method, the Joule effect only slightly affects the phenomenon under consideration.

SIGNOR STRANEO's method forms the basis of a paper by Signor A. Pochettino on variations of the Peltier-effect in a magnetic field. The value of the Peltier-effect coefficient was observed to vary with the magnetisation. In Signor Pochettino's experiments, it increased up to a maximum value of 0·008968, corresponding to a field of ninety-eight units, and then decreased, reaching its normal value (0·008824) in a field of about 345 units, and continuing to decrease as the intensity of the field was further increased. The formula deduced from Houllevigue's experiments, combined with Thomson's formula,

only represents the phenomenon up to a field of 700 units. Lastly, the variation of the Peltier-effect coefficient is independent of the direction of magnetisation; in fact, in suitably-arranged experiments it is found that when the stationary temperature is attained, no changes take place in the thermal conditions of the conductors when the magnetising current is reversed.

In a report received by the Foreign Office, Sir William Garstin has called attention to the need for a scientific examination of the Sudan, with a view to the development of its natural resources. It is pointed out that a very possible source of future wealth to the Sudan lies in the vast forests which line the banks of the Upper Blue Nile and extend, in an easterly direction, to the Abyssinian frontier. In the Bahr-el-Ghazal province also, particularly in the Bongo country, large forest tracts exist. The ebony tree (*Dalbergia melanoxylon*) is met with south of Karkauj, on the Blue Nile, and again in the vicinity of the Sobat River. On the White Nile, in the Bongo and Rohl districts, the india-rubber creeper (*Landolphia florida*) is found in great profusion. If the rubber yielded by this creeper be not of quite so good a quality as that obtained from the Assam india-rubber tree (*Ficus elastica*), it is still of sufficient value to be counted as an important asset in the future trade of the Sudan. The Assam india-rubber tree should certainly flourish well in most parts of the Sudan, more particularly south of Khartoum. Although this tree takes from twenty to thirty years to arrive at a girth sufficient to permit of regular tapping, its yield is so valuable (about 3*l.* per tree per annum) that its introduction into the country is well worth attempting. It is very much to be hoped that a scientific examination of the Sudan forests may ere long be carried out under the superintendence of an expert. It is certain that much valuable information would be obtained from his report. Very little is known regarding the possibilities of mineral wealth in the Sudan. Until the country is more settled, an investigation of the mountainous regions of Kordofan and Darfur on the west, and of the Abyssinian frontier on the east, would be impossible. Iron ore is found in the Bahr-el-Ghazal province, and also in Darfur; while gold mines were at one time worked in the mountains south of Fazogl. Could coal be discovered, it would make a great change in the whole question of the Sudan. In a few years' time it is probable that the Geological Survey Department of Egypt will be able to depute parties to examine the Sudan. For the present, Sir William Garstin thinks nothing can be done.

"Variation and Sexual Selection in Man" is the title of a paper by E. Tenney Brewster in the *Proceedings* of the Boston Society of Natural History (vol. xxix., 1899, p. 45). The author offers evidence to prove that *conspicuous dimensions tend to be more variable than other dimensions*. Not only is the face more variable than the head, but the nose should be more variable than the head; the face without the nose should be more variable than the head; and the nose should be more variable than the rest of the face. The author also suggests that sexual selection has brought it about that parts of the body tend to be more variable in proportion as they are of greater æsthetic value.

The Report of the South African Museum for 1898, issued as a Parliamentary Paper, by the Director, Mr. W. L. Sclater, is satisfactory reading. It appears that in all departments the collections are steadily increasing; while great attention is being paid to the proper exhibition of suitable specimens. In the Geological Department a good collection of the rocks of the Kimberley mining district is already displayed; and steps are being taken for the formation of a complete collection of the economic mineral products of South Africa. This is as it should be; and it is equally satisfactory to learn that the Director is fully alive to the necessity of procuring specimens of all the larger mammals before it is too late. The collection of South African antelopes is indeed complete, with the exception of the Gemsbok and Lichi; and specimens of these ought not to be difficult to procure. It may be hoped that, in addition to the mounted specimens, a study series (if possible in duplicate) of skins may likewise be procured. The only subject the Director has to regret is that he has been unable, chiefly from lack of funds, to continue the work of preparing popular descriptive labels for the exhibited specimens. The hope is, however, expressed that the work may be shortly resumed.

As an excellent bit of work on the local distribution of a species, attention may be directed to Dr. N. H. Alcock's history of the Hairy-armed Bat in Ireland, published in the August number of the *Irish Naturalist*. In England this Bat is found rather abundantly along the Avon valley in Warwickshire, Worcestershire and Gloucestershire; it occurs rarely in Yorkshire, and has been recorded from Cheshire. In Ireland it has been found in most of the north-eastern counties, but nowhere else. We now want to know the reason of this very local distribution; and until this is ascertained our task is but half done.

M. E. Pitard describes in *l'Anthropologie* (x., 1899, p. 281) three crania from Swiss Lake sites. The first from Point, with an index of 91·5, belongs to the Rhetian or Dissentis type, and is remarkably similar to a skull described by M. Verneau from Concise, which that author believed to belong to the Bronze Age; but M. Pitard asserts that his example is Neolithic. The other two crania were found in the same layer at Concise, and are of the Bronze Age; their indices are 77·6 and 84·6.

The Vai or Vei are the only negroes who possess a true and indigenous writing. They occupy a territory on the confines of Sierra Leone and Liberia. The alphabet is syllabic, and it is the only syllabic alphabet existing in Africa. The first account of this remarkable language was published by Forbes and Norris in 1849, and Koelle also wrote on it in 1849 and 1854. Since then nothing has been published thereon till the recent study of M. M. Delafosse (*l'Anthropologie*, Tome x., 1899, pp. 129, 294). Forbes and Koelle asserted that the alphabet was invented about 1829 or 1839, but Delafosse considers it at least two hundred years old and perhaps older; it is not even certain that it was invented by the Vais themselves. Forbes was also wrong in stating that this alphabet was no longer in use in 1849; as a matter of fact, it is still increasingly employed. Of the 226 characters in the alphabet, 25 resemble Berber consonants in form, and 20 resemble European letters and numerals; but these may be purely superficial resemblances, as the sounds do not correspond: the author does not consider that the Vaï alphabet has been derived from these sources.

Sir J. Burdon-Sanderson asks us to notify the following errata in his MS. of the abstract of the Croonian Lecture published in Nature of August 10. On p. 344, col. 1, line 5, for "Fig. 1" read "Fig. 2"; col. 1, line 18, for "Fig. 2" read "Fig. 1"; col. 2, line 12 from the bottom, for "60" read "40."

Part xv. of Mr. Oswin A. J. Lee's elaborate work, entitled "Among British Birds in their Nesting Haunts," has been published by Mr. David Douglas, Edinburgh. The Part contains ten beautiful plates, illustrating the nesting places and nests of the whinchat, osprey, storm petrel, yellow bunting, rook pigeon, Manx shearwater, grey wagtail, and red grouse.

Herr Eugen von Cholnoky contributes to the *Verhandlungen der Gesellschaft für Erdkunde* a short summary of the scientific results of his journeys in China and Manchuria during 1896–98. The most important contributions refer to the geology of the regions visited, and in particular to the positions

of the great lines of faulting crossing Manchuria, indicated by Richthofen.

THE current number of the *Zeitschrift der Gesellschaft für Erdkunde* (vol. xxxiv, No. 2) is entirely devoted to the official reports of the members of the German deep-sea expedition in the *Valdivia*. Prof. Chun gives a narrative of the expedition and its progress; Dr. Gerhard Schott reports on the oceanographical work; and the navigating officer, Herr Walter Sachse, adds an account of the re-discovery of Bouvet Island. A summary of the contents of these reports has already appeared in these columns (p. 114).

A NUMBER of students from the Paris École Supérieure d'Electricité visited electrical works and manufactories in Switzerland at the end of last March, this being the second excursion arranged by the authorities of the School. A report upon some of the objects and installations examined was presented to the Société internationale des Électriciens in May, and has just been published as an excerpt from the *Bulletin* of the Society, by M. Gauthier-Villars, Paris.

THE additions to the Zoological Society's Gardens during the past week include a Vervet Monkey (*Cercopithecus lalandii*) from South Africa, presented by Mr. R. Hilliard; a Brown Capuchin (*Cebus fatuellus*, ♀) from Guiana, presented by Colonel Bourchier; a Common Kingfisher (*Alcedo ispida*), British, presented by Mr. John Porter; an Alexandrine Parrakeet (*Palaeornis alexandri*, ♀) from India, presented by Miss J. M. Pott; a Common Boa (*Boa constrictor*) from South America, presented by Mr. C. W. Lilley; an Alligator (*Alligator mississippiensis*) from Southern North America, presented by Commander H. Woodcock; two Grevy's Zebras (*Equus grevyi*, ♂ ♀) from Southern Abyssinia, a Malayan Bear (*Ursus malayanus*) from Malacca, deposited; three Pink-headed Ducks (*Rhodonessa caryophyllacea*, ♂ ♀ ♀) from India, six Edible Frogs (*Rana esculenta*), European; twelve Paradise Fish (*Macropus viridi-auratus*) from China, purchased; a Japanese Deer (*Cervus sika*), a Puma (*Felis concolor*), a Burchell's Zebra (*Equus burchelli*, ♀), born in the Gardens.

## OUR ASTRONOMICAL COLUMN.

HOLMES' COMET 1899 *d* (1892 III.).—

*Ephemeris for 12h. Greenwich Mean Time.*

| 1899. | R.A. | Decl. | Br. $r^{-2}$ | Br. $(r\Delta)^{-2}$ |

During the ensuing week the comet is in a good position for observation by observers having sufficient optical power; it passes closely to the south of the second magnitude variable star $\beta$ Persei (Algol).

THE PARIS OBSERVATORY.—The annual report of M. Lœwy, the director of the Observatory, contains a detailed review of the work accomplished during the past year.

Special attention has been devoted to the improvement of meridian observations, chiefly in the attempt to eliminate instrumental errors by greater precision and stability of the mountings.

The small equatoral coudé has been provided with several accessories, and the building covering it so altered that the whole is now adapted for astrophysical observations.

The volume of observations made during 1897 will shortly be published in four separate parts, by different authors, who will each be responsible for all reductions, descriptions and discussions contained in the part under their names.

The fourth part of the Paris Observatory Catalogue (of which the first three parts already published contain all the meridian observations made from 1837–1881) has just been completed. The meridian circles have been in use for fundamental observations, for a revision of Lalande's Catalogue, and for work on the variation of latitude.

*Coudé Equatorial.*—The large instrument has been chiefly used in obtaining further series of photographs of the moon (scale about 6·5 inches to the lunar diameter) for the large lunar atlas now in progress of publication. During the year 591 plates have been obtained for this purpose. The method of enlargement of the negatives has also been improved.

Accompanying the report is a heliogravure of the moon when 20d. 5·9h. old, reproduced the same size as the original plate.

For part of the year the photographic objective was replaced by the visual glass, and the instrument then used by M. Hamy for measuring the diameters of small celestial objects by an interference method. The satellites of Jupiter and the planet Vesta have been measured in this way, the diameter of the latter agreeing very closely with the value obtained by Prof. E. E. Barnard.

*Astrographic Equatorial.*—The actual photographic work is now almost completed, all that remains to be done being the replacement of a small number of defective plates. The reduction of the plates for the Catalogue is well in hand, and seven of the Chart plates have been engraved for heliographic reproduction.

"THE BULLETIN ASTRONOMIQUE."—The August number contains several interesting and suggestive articles.—M. Flammarion contributes an article on "The World of Jupiter," in which he discusses at length the question of the various rotation periods of the planet, and also an illustrated account of the observation made by M. Antoniadi at Juvisy during the opposition of June 1898.—"The Rotation of Venus" is treated mathematically by Abbé Th. Moreux, based on observations made at Juvisy by M. Antoniadi.—"Observations of Mars" (illustrated) are contributed by MM. V. Cerulli and J. Chloudoff.—MM. L. Rudaux and Em. Touchet furnish an article on the "Systematic Observation of Meteors," giving a suggested form for recording observations systematically, and dealing with the determination of radiants, the physical characters of the swarms, heights of the meteors, and the photographing of them.

THE SUN'S HEAT.—Prof. T. J. J. See contributes a further article dealing with the extension of Helmholtz's theory of the heat of the sun, in *Astr. Nach.* (Bd. 150, No. 3586). The method he now pursues is the determination of the potential of a heterogeneous sphere as caused by itself. He finds that the energy developed by the condensation on this assumption is greater than that produced in the condensation of a homogeneous sphere in the ratio of 176,868 to 100,000.

## IRON AND STEEL INSTITUTE.

THE autumn meeting of the Iron and Steel Institute was held this year at Manchester, on August 15 and 16, under the presidency of Sir William Roberts-Austen, K.C.B., and was attended by an unusually large number of members. The meetings were held in the Town Hall, the members being welcomed to Manchester in eloquent speeches by the Lord Mayor and by Mr. S. R. Platt, chairman of the Executive Reception Committee. In acknowledging the words of welcome, the President referred to the services rendered to metallurgy by Dalton and Joule, and by such great engineers as Fairbairn, Whitworth and Daniel Adamson, Manchester's distinguished sons. The programme was a long and varied one, no less than ten papers being on the list. The first read was by Prof. J. Wiborgh, of Stockholm, whose contribution, which was translated and read by Mr. H. Bauerman, dealt with the use of finely divided iron ore obtained by concentrating processes. By the introduction of such methods of separation, the power of enriching iron ores has been greatly increased; but the advantages are qualified by the circumstance that the product obtained is usually in the form of fine powder, which limits its utility to the smelter. The question of how such material can best be applied is one of importance, and the author shows how the material may be utilised by direct

addition to the charges in the blast furnace, by agglomeration previously to charging in the blast furnace, as a refining or softening material in the open-hearth furnace, and for the production of sponge iron for use in the open-hearth furnace.

Mr. H. C. McNeill next read a lengthy paper on some forms of magnetic separators and their application to different ores. The machines described were those invented by Wenström, by Delvik-Gröndal, by Heberle, and by Wetherill and the Monarch separator. Results obtained in practice in Sweden were discussed, and numerous illustrations were given. In the discussion of these two papers valuable remarks were made by Mr. James Riley, Mr. G. J. Snelus, F.R.S., Sir Lowthian Bell, Mr. Stead and others.

A new casting machine for blast furnaces was then described by Mr. R. H. Wainford. It is an ingenious apparatus for casting sandless pig iron in insulated moulds, so as to maintain a good crystalline fracture, equal to that of the pig iron made in sand beds, at a reduced cost of production. The advantages and disadvantages of this apparatus were discussed by Mr. E. Windsor-Richards, Mr. W. Hawdon, Mr. Cooper and Sir Lowthian Bell.

Mr. Syed Ali Bilgrami, Secretary to H.H. the Nizam's Government Public Works Department, Railways and Mines, then read a paper on the iron industry in Hyderabad. He described the geological structure of the Nizam's territory, and the various iron ore deposits met with.

Some interesting facts were brought forward by Major R. H. Mahon, of Cossipore, relating to the possibility of manufacturing at a profit iron and steel in India. In the absence of the author this paper was read by the Secretary, Mr. Bennett H. Brough. An interesting discussion followed, in which Mr. Bauerman and Mr. R. Price-Williams took part. The meeting was then adjourned until Wednesday, when a paper by Mr. C. H. Ridsdale was read. The microscopic examination of steel is a subject on which a good deal has been written during the last few years. Most of the papers hitherto published have dealt with the matter from a purely scientific point of view. The aim of the exhaustive paper contributed by Mr. C. H. Ridsdale was to show the practical value of the microscope to the steel maker and user at the present day. The time has now arrived, he points out, when it should be recognised that composition only indicates such well-defined effects as are generally understood without certain narrow limits of treatment, which are termed "normal." Outside these limits the effect of the treatment far outweighs that of the composition. In the discussion of this paper the President, Mr. Greiner, Mr. Harbord and Mr. Stead took part.

Mr. J. W. Miller contributed a paper on pig iron fractures and their value in foundry practice. He gave instances of the loss sustained by the manufacture of pig iron owing to the present method of grading pig iron by fracture.

The present position of the solution theory of carburised iron was discussed by Dr. A. Stansfield. The conclusions he has arrived at with respect to the atomic complexity in carbon are as follows:—

The carbon in molten iron is in a state of simple solution; the molecule of carbon must then contain one or two atoms, and is probably monatomic. The solidified iron is in the $\gamma$ state and contains free carbon in solution. The molecular weight of this carbon has not been discussed, but it is probably the same as that in the molten iron. The carbon in solid solution combines with iron, on cooling, to form a carbide, which is probably expressed by the formula $2(Fe_3C)$. When, on further cooling, this carbide falls out of solution as cementite, its formula may become more complicated; the solution theory affords no information on this point; but Sir W. Roberts-Austen stated in his presidential address that the nature of the products of its solution in acids led to the conclusion that the molecule may contain six atoms of carbon, and is at least as complex as would be indicated by the formula $6(Fe_3C)$. There appears to be a belief that the solution theory is in a sense opposed to, and has gone far to supplant, the older allotropic theory; but this paper will, it is hoped, effectually dissipate such an error, as it shows how entirely the solution theory of the relations of carbon and iron involves the allotropic changes with which the distinguished name of Osmond is so inseparably connected.

In the discussion of this paper Mr. Snelus, Mr. Hadfield and Mr. Stead took part.

Mr. A. Sauveur, of Boston, contributed a paper on the changes of structure brought about in steel by thermal and mechanical treatment. He showed that as the smaller the grains of the metal the more ductile and tough it will be, as the finest possible structure results from heating to Brinell's point W, the temperature at which the passage of cement carbon into hardening carbon during the heating of steel takes place, namely, 655° to 730° C., it is evident that every finished piece of unhardened steel should as a last treatment be heated to that temperature.

Prof. E. D. Campbell, of Ann Arbor, Michigan, contributed a paper on the constitution of steel. The general method employed for studying the products of steel was to dissolve the steel in hydrochloric acid, pass the gas evolved through bromine in order to convert unsaturated hydrocarbons of the general formula $C_nH_{2n}$ into their di-brom derivatives $C_nH_{2n}Br_2$; the gas passing through the bromine being measured, and the carbon existing as gaseous paraffins being determined by explosion and absorption of the carbon dioxide produced. The di-brom derivatives, after proper purification, drying, and weighing, were analysed and fractionally distilled for the purpose of qualitatively identifying the various constituents; although the fractional distillation of the di-brom derivatives had shown the presence of ethylene, propylene, butylene, pentylene, and hexylene di-bromides, and dibutylene tetrabromide, later investigations had shown that this last product was the result of the polymerisation under the influence of heat during distillation of butylene di-bromide, and was not present to any considerable extent, at least in the original derivatives. Although the di-brom derivatives from ethylene dibromide ($C_2H_4Br_2$) to hexylene dibromide ($C_6H_{12}Br_2$) had been detected qualitatively, the separation of the various derivatives by fractional distillation *in vacuo* was not sufficiently sharp to give accurate quantitative results in regard to the amount of each constituent present. From the percentage of bromine in the di-brom derivatives the average number of carbon atoms in the molecule was calculated, the results of the examination of a few samples of steel by the above method being shown in the following table:—

| Name. | Heat treatment. | Per cent. of carbon of steel. | Per cent. of carbon as derivatives. | Per cent. of carbon as gaseous paraffins. | Per cent. of carbon unaccounted for. | Per cent. of bromine in derivatives. | Calculated carbon atoms in carbon molecule of derivatives. |
|---|---|---|---|---|---|---|---|
| F | Annealed | 0·55 | 37·1 | 33·6 | 29·3 | 72·56 | 4·32 |
| F | Hardened and tempered | 0·55 | 25·0 | ... | ... | 75·65 | 3·67 |
| C | Annealed | 1·14 | 43·4 | 37·9 | 18·7 | 73·85 | 4·05 |
| C | Hardened | 1·14 | 29·0 | 48·6 | 22·4 | 77·61 | 3·31 |
| D | Annealed | 1·28 | 31·0 | 44·3 | 24·7 | 77·80 | 3·26 |
| | Pure Carbide from D anneal'd | 6·64 | 35·3 | 25·2 | 39·5 | ... | 4·41 |

The number of carbon atoms in the carbon molecule of the derivatives from the pure carbide, given in the above table, was obtained from the analysis of the gas by dividing the volume of carbon dioxide, produced from the explosion of the olefines, by the volume of the olefines exploded. The hypothesis suggested by the author made the fundamental assumption that carbon formed with iron a series of compounds which might properly be termed "ferrocarbons," on account of their similarity in structure to hydrocarbons. This series of ferrocarbons had the empirical formula $(CFe_3)_n$; or, $C_nFe_{3n}$, and should be considered as being derived from the hydrocarbons of the olefine series with the general formula $C_nH_{2n}$ by the replacement of the $H_2$ by the bivalent group $Fe_3$. These ferrocarbons, dissolved in hydrochloric acid, yield as their primary products of solution the corresponding olefines and hydrogen.

During the meeting excursions were arranged to the locomotive works at Horwich, to the Simon-Carves coke ovens near Barnsley, to the Manchester Ship Canal, to the ironworks of Platt Brothers, Ltd., at Oldham, to the boiler works of Galloways, Ltd., and to the steel works at Crewe; and hospitality was lavishly dispensed to the members by the Duke of Devonshire at Chatsworth, by the Lord Mayor of Manchester, and by the Mayor of Salford.

## MAGNETO-OPTIC ROTATION AND ITS EXPLANATION BY A GYROSTATIC SYSTEM.[1]

II.

I MUST now endeavour to give some slight account of the theories that have been put forward in explanation of magneto-optic rotation. There is an essential distinction between it and what is sometimes called the natural rotation, the plane of polarised light produced by substances, such as solutions of sugar, tartaric acid, quartz, &c., some of which rotate the plane to the right, some to the left. When light is sent once along a column of any of those substances without any magnetic field, its plane of rotation is rotated just as it is in heavy glass or bisulphide of carbon in a magnetic field. But if the ray, after passing through the column of sugar or quartz, is received on a silvered reflector and sent back again through the column to the starting point, its plane of polarisation is found to be in the same direction as at first. Quite the contrary happens when the rotation is due to the action of a magnetic field. Then the rotation is found to be doubled by the forward and backward passage, and it can be increased to any required degree by sending the ray backward and forward through the substance, as shown in this other diagram (Fig. 8).

Thus the rotations in the two cases are essentially different, and must be brought about by different causes. In fact, as was first, I believe, shown by Lord Kelvin, the annulment of the turning in quartz, and the reinforcement of the turning in a magnetic field, produced by sending the ray back again after reflection at the surface of an optically denser medium, points to a peculiarity of structure of the medium as the cause of the turning of the plane of polarisation in sugar solutions and quartz, and to the existence of rotation in the medium as the cause of the turning in a magnetic field. Think of an elastic solid, highly incompressible and endowed with great elasticity of shape and of the same quality in different directions—a stiff jelly may be taken as an example to fix the ideas. Now let one portion of the jelly have bored into it a very large number of extremely small corkscrew-shaped cavities, having their axes all turned in the same direction. Let another portion have imbedded in it a very large number of extremely small rotating bodies, spinning-tops or gyrostats in fact, and let these be uniformly distributed through the substance, and have their axes all turned in the same direction.

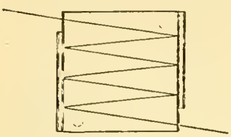

FIG. 8.

Both portions would transmit a plane-polarised wave of transverse vibration travelling in the direction of the axes of the cavities or of the tops with rotation of the plane of polarisation; but in the former case the wave, if reflected and made to travel back, would have the original plane of polarisation restored; in the latter the turning would be doubled by the backward passage.

To understand this it is necessary to enter a little in detail into the analysis of the nature of plane-polarised light. As I have already said, the elastic solid theory may not express the facts of light propagation, but only a certain correspondence with the facts. But its use puts this matter in a very clear way. In a ray of plane polarised light each portion of the ether has a motion of vibration in a line at right angles to the ray, and the direction of this line is the same for each moving particle. The lines of motion and the relative positions of the particles in a wave are shown in the first diagram (Fig. 1 p. 379). As the motion is kept up at the place of excitation, it is propagated out by the elastic resistance of the medium to displacement, and the configuration of particles travels outwards with the speed of light, traversing a wave-length (represented in the diagram by the distance between two particles of the row in the same phase of motion) in the period of complete to-and-fro motion of a particle in its rectilineal path.

Now, a to-and-fro motion such as this can be conceived as made up of two opposite uniform and equal circular motions. Think of two distinct particles moving in the two equal circles A B in this diagram (Fig. 9), with equal uniform speeds in opposite directions. Let each particle be at the top of its circle at the same instant; then at any other instant they will be in similar positions, but one on the right, the other on the left of the vertical diameter of the circle. Thus at that instant each particle is moving downward or upward at the same speed, while with whatever speed one is moving to the left, the other is moving with precisely that speed towards the right. Imagine now these two motions to be united in a single particle. The vertical motions will be added together, the right and left motions will cancel one another, and the particle will have a motion of vibration in the vertical direction of range equal to twice the diameter of the circles, and in the period of the circular motions.

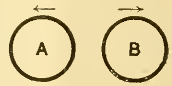

FIG. 9.

The rate of increase of velocity of the particle at each instant is the resultant obtained by properly adding together the accelerations of the particles in the circular motions, and therefore the force which must act on the particle to cause it to describe the vibratory motion just described is the resultant of the forces required to give to the two particles the circular motions which have just been considered.

Now, what we have done for any one particle may be conceived of as done for all the particles in a wave. To understand the nature of a wave in this scheme, we must think of a series of particles originally in a straight line in the direction of propagation of the ray, as displaced to positions on a helix surrounding that direction. Fig. A of this diagram (Fig. 10), regarded from the lower end, and the black spots on the model before you, show a left-handed helical arrangement. Let these particles be projected with equal speeds in the circular paths represented by the circle at the bottom of Fig. A. On this circle are seen

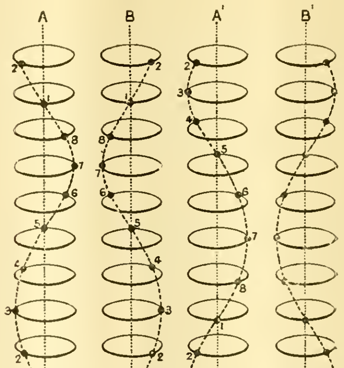

FIG. 10

the apparent positions of different particles in the helical arrangement when it is viewed by an eye looking upwards along its axis. This motion is shown by that of the black spots on the surface of the model (Fig. 11), when I set it into rotation about its axis. Let the particles be constrained to continue in motion exactly in this manner. As the model shows, the helical arrangement of the particles is displaced along the cylinder. This is the mode of propagation of a *circularly* polarised wave, which is made up of helical arrangements of particles which were formerly in straight lines parallel to the axis.

The direction of propagation of the wave is clearly from the

[1] A discourse delivered at the Royal Institution by Prof. Andrew Gray, F.R.S. (Continued from p. 381.)

bottom of the diagram to the top, and from the end of the model towards your left to the other, when the particles have a right-handed motion, and is in the contrary direction when the direction of rotation is reversed. For a right-handed helical arrangement the direction of propagation for the same direction of motion of the particles is the opposite of that just specified. The direction of propagation remains, therefore, the same when the direction of motion and the helical arrangement of the particles are both reversed. All this can be made out from the diagram. Fig. B shows part of a right-handed arrangement of

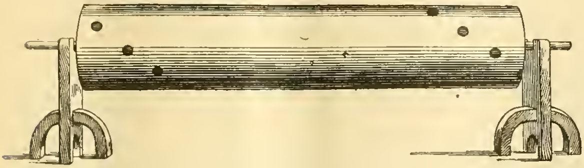

FIG. 11.

particles corresponding to the opposite arrangement of Fig. A; and if the particles have the motions shown at the bottom of the diagram the propagation will be for both in the same direction, from the bottom to the top.

In Fig. 10 we suppose the periods equal and also the wave-lengths, the distance along the axis from particle 1 to particle 9. The combination of the circular motions A and B gives rectilinear motion; the combination of the wave motions of Figs. A and B gives a plane polarised wave the plane of polarisation of which does not change in position. If, however, while the periods were equal, the wave-lengths were unequal as shown in this other diagram (Fig. 12), the plane of polarisation would rotate, as shown by the lines drawn across the paths in the figure on the right, for the circular motions of particles in the longer wave would gain on those in the shorter.

A little consideration will show that the direction of the resultant rectilinear motion will, in consequence of the unequal speeds of propagation, turn round as the wave advances, and will do so in the direction of motion of the particles in the more quickly travelling wave, generating the screw surface shown in the model I have already exhibited.

We must now consider the forces. The particles moving in the circular paths have accelerations towards the centres of these paths, and forces must be applied to them to produce these accelerations. These forces are applied in the present theory by the action of the medium, and it is the reactions of the particles on the medium that are properly called the centrifugal forces of the particles. The requisite centreward forces then are supplied by the state of strain into which the medium is thrown by the displacement of parts of it, which form in the undisturbed position a series of straight arrays in the direction of propagation, into these helical arrangements round that direction. The greater these elastic forces the greater the velocity of propagation of the wave.

In an elastic medium these forces depend on the *amount* of the relative displacements of the particles, and will be greater for displacements in the right-hand helical arrangement than for displacements in the opposite direction if the medium has a greater rigidity for right-handed distortion than for left, and the right-handed wave of distortion will be transmitted with greater speed, and *vice versâ*. This is the case of solutions of sugar and tartaric acid, quartz, &c., for which a helical structure has been supposed to exist in the medium.

Taking this case refer to Figs. A and B of our large diagram (Fig. 10), and let the right-handed wave travel the faster. Let the waves travel up, be reflected at the upper ends, as at the surface of a denser medium, and then travel down again. The reflected waves are those shown in Figs. A′, B′ of the diagram. By the reflection, the helical arrangement will be unaltered. But the plane of polarisation, as we have seen, turns round in space in the direction of the motion of the particles in the more quickly moving wave; it therefore turns round in the direction of the hands of a watch as the wave moves in the upward direction in the diagram, and in the opposite direction when the wave is travelling back. Thus the rotation of the plane of polarisation produced in the forward passage is undone in the backward.

It is easy to see that the same thing will take place if the reflection is at the surface of an optically rarer medium, so that the direction of motion of the particles is the same in the reflected as in the direct wave. The helical arrangements, however, are reversed by the reflection, and hence the wave which travelled the more quickly forward travels the more slowly back, and again the turning of the plane of polarisation is annulled by the backward passage. Thus Lord Kelvin's hypothesis of difference of structure completely explains the phenomena.

We pass now to the other case, that of magneto-optic rotation. Let us suppose, to fix the ideas, that the right-handed circular ray travels faster than the other, and that whether direct or reversed. Here, as in the other case, the elastic reaction of the medium on the displaced particles depends only on the distortion, and if there be no structural peculiarity in the medium there must be the same reaction in the particles in both the circular waves which combine to make up the plane-polarised one.

Thus the actions on the particles being the same for both waves, and the velocities of propagation being different, the motions concerned in the light propagation cannot be the same. There must in fact be a motion already existing in the medium which, compounded with the motions concerned in light propagation, give two motions which give equal reactions in the medium against the equal elastic forces, applied to the particles in the case of equal helical displacements.

Thus Lord Kelvin supposes that in the medium in the magnetic field there exists a motion capable of being compounded

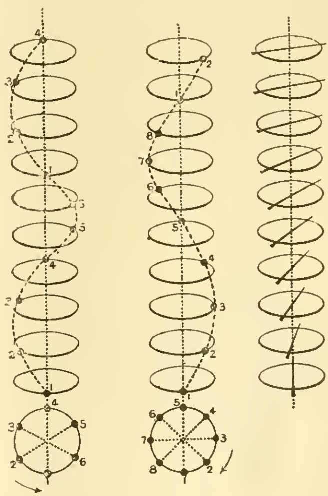

FIG. 12.

with the luminiferous motion of either circularly polarised beam. The latter is thus only a component of the whole motion.

In the very important paper in which he has set forth his theory Lord Kelvin expresses his strong conviction that his dynamical explanation is the only possible one. If this view be correct, Faraday's magneto-optic discovery affords a demonstration of the reality of Ampère's theory of the ultimate nature of magnetism. For we have only to consider the particles of a magnetised body as electrons or groups of charges of electricity, ultimate as to smallness, rotating about axes on the whole in

alignment along the direction of the magnetic force, and with a preponderance of one of the two directions of rotation over the other. Each rotating molecule is an infinitesimal electromagnet, of which the current distribution is furnished by the system of convection currents constituted by the moving charges.

The subject of magneto-optic rotation has also been considered by Larmor, and two types of theory of these effects have been indicated by him in his report on the "Action of Magnetism on Light." One is represented by Lord Kelvin's theory, which is illustrated by Maxwell's chapter on molecular vortices in his "Electricity and Magnetism." FitzGerald's paper "On the Electromagnetic Theory of the Reflection and Refraction of Light," in the *Philosophical Transactions* for 1880, is related to Maxwell's theory, and explains the rotation produced by reflection from the pole of a magnet by means of the addition of a term to the energy of the system. The other theory is also a purely electromagnetic one, and supposes that the effects are due to a kind of æolotropy of the medium set up by the magnetisation, and so attributes them to a change of structure which introduces rotational terms into the equations connecting *electric* displacements and electric forces. This latter theory therefore regards the magneto-optic rotation as only a secondary effect of the magnetisation, which is not supposed to exert any direct dynamical influence on the transmission of the light-waves.

It is not possible here to enter into the subject of these theories, but I should like to direct attention to a paper by Mr. J. G. Leathem, published in the *Philosophical Transactions*, in which the type of theory just referred to has been worked out and compared in its results with the experiments of Sissingh and Zeeman in reflection. These investigators made measurements of the phase and amplitude of the magneto-optic component of the reflected light for various angles of incidence. For both these quantities the theoretical results of Leathem agree very well with the observed values.

Returning now to the gyrostatic medium, between which and the electromagnetic theory, it is to be remembered, there is a correspondence, we may inquire in what way the gyrostats, when moved by the vibrations of the medium, react upon it, and so affect the velocity of propagation. The motion of a gyrostat is often regarded as mysterious, and it can hardly be fully explained except by mathematical investigation. But the general nature of its action may be made out without much difficulty. First of all, a gyrostat consists of a massive fly-wheel running on bearings attached to a case which more or less completely encloses the wheel. The mass of the wheel consists in the main of a massive rim, which renders as great as possible what is called the moment of momentum of the wheel when rotating about its axis. The diagram (Fig. 13) represents a partial section of the case and fly-wheel of a gyrostat, showing the arrangement of fly-wheels and bearings.

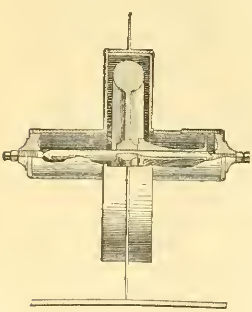

FIG. 13.

Now let the fly-wheel of such a gyrostat be rapidly rotated, and the gyrostat be hung up as shown in this other diagram (Fig. 14), with the plane of the fly-wheel vertical, and a weight attached to one extremity of the axis. The gyrostat is not tilted over, but begins to turn round the cord by which it is suspended with a slow angular motion which is in the direction of the horizontal arrow, if the direction of rotation is that of the circular arrow shown on the case. The same thing is shown by the experiment I now make. I spin this gyrostat and hang it with the axis of rotation horizontal by passing a loop of cord round one end of the axis so that the weight of the gyrostat itself forms the weight tending to tilt it over about the point of suspension. The axis of rotation here again remains nearly horizontal, but turns slowly round in a horizontal plane as before.

The explanation in general terms is this. The weight gives a couple tending to turn the gyrostat about a horizontal axis at right angles to that of rotation. This couple in any short interval of time produces moment of momentum about the axis specified, the amount of which is the moment of the couple multiplied by the time, and may be represented in direction and magnitude by the line OB. This must be compounded with the moment of momentum OA already existing about the axis of rotation, and gives for the resultant moment of momentum the line OC, which is the direction of the axis of rotation after the lapse of the short interval of time. The axis of rotation thus turns slowly round in the horizontal plane, and the more slowly the more rapidly the fly-wheel rotates.

The gyrostat in fact must have this precessional motion, as it is sometimes called, in order that the moment of momentum of the gyrostat about a vertical axis may remain zero. That it must remain zero follows from the fact that there is no couple in a horizontal plane acting on the gyrostat.

Thus any couple tending to change the direction of the axis in any plane produces a turning in a perpendicular plane. For example, if a horizontal couple, that is about a vertical axis, were applied to the axis of the gyrostat in the last figure it would turn about a horizontal axis, that is, would tilt over.

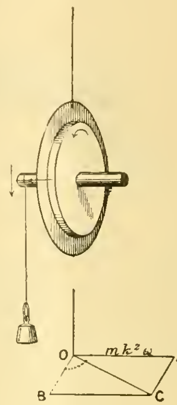

FIG. 14

Again, consider a massive fly-wheel mounted on board ship on a horizontal axis in the direction across the ship. The rolling of the ship changes the direction of the axis, and produces a couple applied by the fly-wheel to the bearings and an equal and opposite couple applied by the bearings to the fly-wheel. This couple is in the plane of the deck, and is reversed with the direction of rolling, and has its greatest value when the rate of turning of the ship is greatest. Thus the force on one bearing is towards the bow of the ship, the force on the other towards the stern, during a roll from one side to the other; and these forces are reversed during the roll back again. This is the gyrostatic couple exerted on its bearings by the armature of a dynamo on shipboard.

In the same way, when a gyrostat is embedded in a medium and the medium is moving so as to change the direction of the axis of rotation, a couple acting on the medium in a plane at right angles to the plane of the direction of motion is brought into play. To fix the ideas, think of a row of small embedded gyrostats along this table with their axes in the direction of the row, and their fly-wheels all rotating in the same direction. Now let a wave of transverse displacement of the medium in the vertical direction pass along the medium in the direction of the chain. The vibratory motion of each part of the medium will turn the gyrostatic axis from the horizontal, and thereby introduce horizontal reactions on the medium. Again, a wave of horizontal vibratory motion will introduce vertical reactions in the medium from the gyrostats.

Now, a wave of circular vibrations, like those we have already considered, passing through the medium in the direction of the chain, could be resolved into two waves of rectilinear vibration, one in which the vibration is horizontal, and another in which the vibration is vertical, giving respectively vertical and horizontal reactions in the medium. The magnetisation of the medium is regarded as due to the distribution throughout it of a multitude of rotating molecules, so small that the medium, notwithstanding their presence, seems of uniform quality. The molecules have, on the whole, an alignment of their axes in the direction of magnetisation. These reactions on the medium when worked out give terms in the equations of wave propagation of the proper kind to represent magneto-optic rotation.

It is worthy of mention that the addition of such terms to the equation was made by McCullagh, the well-known Irish mathematician, who, however, was unable to account for them by any

physical theory. The necessary physical theory may be regarded as afforded by the mechanism which thus forms an essential part of Lord Kelvin's mode of accounting for magneto-optic effects.

Lord Kelvin, in his Baltimore Lectures, has suggested for magneto-optic rotation a form of gyrostatic molecule consisting, as shown in the figure, of a spherical sheath enclosing two equal gyrostats. These are connected with each other and with the case by ball-and-socket joints at the extremities of their axes, as shown in Fig. 15. If the spherical case were turned round any axis through the centre no disalignment of the gyrostats contained in it would take place, and it would act just like a simple gyrostat. If, however, the case were to undergo translation in any direction except along the axis, the gyrostats would lag behind, and the two-link chain which they form would bend at the centre. This bending would be resisted by the quasi-rigidity of the chain produced by the rotation, and the gyrostats would react on the sheath at the joints with forces as before at right angles to the plane in which the change of direction of the axis takes place.

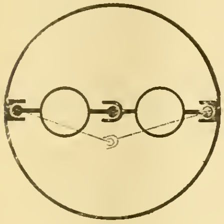

FIG. 15.

The general result is, that if the centre of this molecule be carried with uniform velocity in a circle in a plane at right angles to the line of axes, the force required for the acceleration towards the centre, and which is applied to it by the medium, is greater or less according as the direction in which the molecule is carried round is with or against the direction of rotation of the gyrostats. That is, the effect of the rotation is to virtually increase the inertia of the molecule in the one case and diminish it in the other.

These molecules embedded in the medium are supposed to be exceedingly small, and to be so distributed that the medium may, in the consideration of light propagation, be regarded as of uniform quality. Lord Kelvin's last form of molecule, it may be pointed out, if the surface of its sheath adheres to the medium, will have efficiency as an ordinary single gyrostat as regards rotations of the molecule, and efficiency likewise as regards translational motion of the centre of the molecule. The former efficiency can be made as small as may be desired by making the molecule sufficiently small; the latter may be maintained at the same value under certain conditions, however small the molecule be made.

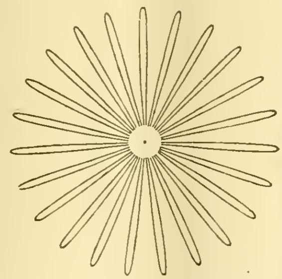

FIG. 16.—Path of the Bob of a Gyrostatic Pendulum. As the pendulum moves, it passes from one ray to another on the opposite side, and the direction of motion at each swing alters through the angle between two rays. The central parts of the rays are left out. The marking point does not pass exactly through the centre.

The lately discovered effect of a magnetic field in giving one period of circular oscillation of a particle or another according as the particle is revolving in one direction or the other about the direction of the magnetic force, is connected with magneto-optic rotation. There is a connection between velocity of propagation and frequency of vibration, which is exemplified by the phenomena of dispersion. In the Faraday effect, the two modes of vibration, if of the same period, have different velocities of vibration, consequently these two modes of vibration must have different frequencies for the same velocity of propagation.

The vibrations of the molecules of a gas in which the Zeeman effect is produced by a magnetic field may be represented by the motion of a pendulum the bob of which contains a rapidly rotating gyrostat with its axis in the direction of the supporting wire of the pendulum. The period of revolution of the bob when moving as a conical pendulum is greater or less than the period when the gyrostat is not spinning according as the direction of revolution is against or with the direction of rotation.

The bob when deflected and let go moves in a path which constantly changes its direction, so that if a point attached to the bob writes the path on a piece of paper, a star-shaped figure is obtained. I cause the gyrostatic pendulum here suspended to draw its path by a stream of white sand on the black board placed below it, and you see the result.

I must here leave the subject, and may venture to express the hope that on some other occasion some one more specially acquainted with the electromagnetic aspects of the phenomenon may be induced to place the latest results of that theory before you.

## UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

MR. JAMES BROWN THOMSON, of Kinning Park, Glasgow, who died ten months ago, left 80,000*l.* to Glasgow institutions—mostly educational and benevolent. The Glasgow University will receive 10,000*l.*

THE recent discussion in NATURE on "The Duties of Provincial Professors" forms the subject of a short critique in the August number of the *Educational Review*. While fully endorsing the general views expressed in our columns, the *Review* remarks: "There is only one flaw in the indictment—the insinuation, namely, that university professors should take no part in the social life and physical activities, the general discipline, the corporate existence of the university or university college." But where does this flaw exist? No such insinuation is made in the article in NATURE.

THE Department of Science and Art has issued the following list of successful candidates for Royal Exhibitions, National Scholarships, and Free Studentships (Science) awarded this year:—Royal Exhibitions: William M. Selvey, Edward C. Moyle, Archibald D. Alexander, Charles W. Price, George F. A. Cowley, Edgar Sutcliffe, Sydney A. Edmonds. National Scholarships for Mechanics: Francis P. Johns, George F. Turner, Walter A. Scoble, Arthur J. Spencer, William H. Adams. Free Studentships for Mechanics: R. Borlase Matthews, William H. Outfin. National Scholarships for Physics: William R. Daniel, William J. Lyons, James Lord, William M. Varley, Wilfred H. Clarke. Free Studentships for Physics: John H. Shaxby, Gerald Henniker. National Scholarships for Chemistry: William D. Rogers, John H. Crabtree, Howard E. Goodson, Arthur H. Higgins, Montague W. Stevens. Free Studentships for Chemistry: John R. Horsley, Arthur C. Nicholson. National Scholarships for Biology: Eric Drabble, Louis E. Robinson, Ernest A. Wraight, Reginald F. G. Bayley, Harold B. Fantham. National Scholarships for Geology: William H. Goodchild, Thomas Thornton.

THE following list of candidates, successful in this year's competition for the Whitworth Scholarships and Exhibitions, has been received from the Department of Science and Art:—Scholarships, tenable for three years, 125*l.* a year each: Alec W. Quennell, London; Hanson Topham, Great Horton, Bradford; William V. Shearer, Langside, Glasgow; George Wall, Oldham. Exhibitions, tenable for one year, value 50*l.* each: Arthur J. Spencer, Portsmouth; George F. Turner, Sheffield; Harold P. Philpot, London; William H. Adams, Devonport; Edward C. Moyle, Devonport; Walter A. Scoble, E. Stonehouse, Devon; Archibald D. Alexander, Portsmouth; Sydney A. Edmonds, Devonport; George F. A. Cowley, Portsmouth; Albert Wilson, Leeds; Edwin J. Britton, Portsmouth; Harry Duncan, Plumstead; Samuel C. Rhodes, Morley, Leeds; Harry M. Andrew, Manchester; Alexander P. Traill, North Shields; Leonard Bairstow, Halifax; William T. S. Butlin, Bristol; Albert E. Dodridge, Devonport; James Lowe, Alloa; William J. Rodd, Plumstead; Francis C. Rendle, Plymouth; Thomas E. Heywood, Cardiff; James Paul, Woolwich; Charles P. Raitt, Portsmouth; Charles H. Booth, Bolton; Edward Howarth, Oldham; Percy Down, London; Marshall H. Straw, Sneinton, Nottingham; R. Borlase Matthews, Swansea; Samuel Crossley, Oldham.

## SOCIETIES AND ACADEMIES.

EDINBURGH.

**Royal Society**, July 17.—The Hon. John Abercromby in the chair.—The Keith prize for the period 1895–97 was awarded to Dr. Thomas Muir, for his valuable mathematical papers published in the *Transactions* and *Proceedings*. The Makdougall-Brisbane prize for the period 1896–98 was awarded to Dr. William Peddie, for his experimental researches on the torsion of wires, his discussion of a unique case of colour-blindness, and other investigations in physical science. The Neill prize for 1895–98 was awarded to Prof. Cossar Ewart, for his important investigations bearing on the theory of heredity.—A paper by Lord Kelvin, on magnetism and molecular rotation, was communicated, the main conclusion of which was that a gyrostatic molecule could not in a strong magnetic field give the Zeeman effect. Only a broadening of the lines, not a splitting, could occur. This agreed with Larmor's statement; and the probability was that Lorentz's theory was essentially true.—Sir John Murray and Mr. F. P. Pullar read a first instalment of their account of a bathymetrical survey of the Scottish fresh-water lochs. These could be divided into two great classes, the deep and the shallow. The shallow lochs varied considerably in temperature throughout the year—a fact which had an important bearing on the forms of animal life frequenting these lochs. The lochs discussed were Lochs Katrine, Arklet, Achray, Vennacher, Drunkie, Voil, Doine, and Lubnaig. 2422 soundings had been taken. The greatest depth observed in Loch Katrine was 495 feet; and about one square mile of the bottom of this loch was below sea level. The portable sounding machine used had been designed by Mr. Pullar.—Dr. Hepburn exhibited a new osteometric board, the idea of which was to keep the vertical sliding piece always perfectly parallel to itself. This was effected by means of two brass rods parallel to each other and parallel to the graduated board. These passed through holes in the vertical sliding piece. By this simple device all irregularities in successive measurements of the same bone were quite done away with.

PARIS.

**Academy of Sciences**, August 14.—M. Maurice Lévy in the chair.—Researches on the metallic derivatives of acetylene, by MM. Berthelot and Delépine. Thermochemical experiments on the compounds of acetylene with silver, silver nitrate, silver sulphate, silver chloride and iodide. Dry silver acetylide, $Ag_2C_2$, detonates when heated in a vacuum with production of a reddish flame. The authors discuss the nature of this explosion, since the products being solids, silver and carbon, no flame would be expected. The conclusion is arrived at that the temperature of the reaction is sufficient to volatilise the carbon, and that the flame is gaseous carbon at a very high temperature approaching 4000° C.—Reaction of argon and nitrogen with mercury alkyls, by M. Berthelot. Mercury methyl, $Hg(CH_3)_2$, submitted in an atmosphere of argon to the action of the silent electric discharge, forms no compound with argon, although when the argon is replaced by nitrogen the latter is readily absorbed. With mercury phenyl, $Hg(C_6H_5)_2$, a slight absorption of argon is noticeable, amounting to about 5 per cent. in twenty-three hours.—Observations of Tempel's Comet (1873 II.), made at the Observatory of Paris (with the 30·5 centimetre equatorial), by M. G. Fayet. The observations were carried out on the nights of July 31, August 9 and 10. The comet was at its brightest on July 31, although very low down on the horizon.—Observations of the Perseids of 1899, by Mlle. D. Klumpke. These observations were made under very favourable conditions of sky between August 9 and 13.—On the shower of shooting stars (Perseids) at Lyons, and a remarkable meteor, by M. Ch. André. The August showers of shooting stars were relatively small in number at Lyons. On the evening of the 11th a remarkable meteor was seen starting at about 10·43 p.m. from the constellation of Hercules. It was bluish-white at first, changing abruptly in colour to an orange-red. It was under observation for four seconds.—On the correspondence between right lines and spheres, by M. O. E. Lovett.—On the black pottery earths, by M. H. Le Chatelier. The property of producing black ware by the action of air charged with tar vapour at a high temperature is found to be intimately related with the presence of iron in the earth; in the absence of iron, a greyish coloration at the most is produced in the interior, nearly all the carbon remaining in the outside crust. The most satisfactory results were obtained by acting with acetylene for a quarter of an hour at 450° to 480° upon an earth containing about 2 per cent. of iron oxide. The objects are then removed to a furnace and baked at about 1200°, the hardness thus obtained being comparable with that of porcelain.—On Egyptian porcelain, by M. H. Le Chatelier.—Action of sodammonium and potassammonium upon tellurium and sulphur, by M. C. Hugot. With the alkali in excess the products were $Na_2S$, $K_2S$, $Na_2Te$, $K_2Te$, all white amorphous substances, soluble in water, but insoluble in liquid ammonia, and incapable of absorbing ammonia. With the sulphur or tellurium in excess, the products are $Na_2S_5$, $K_2S_5$, $Na_2Te_3$, $K_2Te_3$, all crystalline, soluble in water and in liquid ammonia, and capable of absorbing ammonia gas.—On the composition of the albumen of the seed of the carob tree, by MM. Em. Bourquelot and H. Hérissey. It has been shown in a previous paper by the authors that a mixture of mannose of galactose results from the careful hydrolysis of the albumen from carob seeds. It is now found that four-fifths of this albumen is constituted by a mixture of the anhydrides of mannose and galactose (mannane and galactane). The carob seed is a very advantageous source of crystallised mannose.—Detection and estimation of free phosphorus in oils and fatty bodies, by M. E. Louïse. The oil or fat is dissolved in twenty times its volume of ordinary acetone, and a concentrated solution of silver nitrate added. The silver produced is assumed to be proportional to the amount of free phosphorus present.—On the coloration of the Tunicates and the mobility of their pigmentary granules, by M. Antoine Pizon.—Action of different luminous radiations upon silkworms in different stages, by M. C. Flammarion.

## PLANTS AND THEIR ENVIRONMENT.

*Les Végétaux et les Milieux Cosmiques (Adaptation–Evolution).* Par J. Constantin. Pp. 292. Avec 171 gravures dans le text. (Paris: Félix Alcan, 1898.)

THIS little book has some admirable points which can be urged in its favour, and it also exhibits lacunæ which are a source of irritation to the reader. Chief amongst its more obvious defects is the entire lack of reference to literature. In a book of this sort such references are particularly desirable, as it will be read by many who may have no special first-hand acquaintance with the sources whence M. Constantin draws his facts.

The book is well conceived and clearly written, though of course it makes no claims to be considered as an exhaustive treatise.

The various kinds of surroundings in which different plants live, and the nature of the corresponding response on the part of the plant organism forms the main thesis of the book. An example will serve to illustrate the author's method.

The cold temperate climate on the whole tends to favour the production of dwarf plants, whereas the colder seas, as is well known, are the home of the largest algæ. Ultimately both of these apparently contradictory effects are to be explained on nutritional grounds, the short period of terrestrial vegetation, during which alone assimilation can proceed, is to be contrasted with the more equable temperature of the sea, and especially with the fact that nutrition is favoured, in the case of aquatics, by lower temperatures, since gases are more soluble, and hence more abundantly at the disposal of the organism, than would be the case in warmer water.

Similarly, the effects of light, gravity and aquatic surroundings upon the structure and form of plants are discussed, and the reader will find much to interest him in the pages which deal with these topics. At the same time it must be confessed that the treatment strikes one as somewhat superficial at times, especially when the author wanders into the paths of theoretical interpretation.

M. Constantin shares the belief, emphatically held by some German botanists, in the direct influence of the environment not only as modifying the form in the individual but also as impressing, without the aid of natural selection, that form on the species as part of its inherited stock; and one chapter is devoted to an attempt to establish the thesis that acquired characters are inherited. As usual, however, in such cases, the meaning of "acquired characters" is not rigidly defined, nor separated from latent possibilities in the organism which the environment is able to emphasise simply by providing that stimulus which ensures their positive appearance.

Some of these variations, responsive to the external requirements, are certainly very difficult of explanation on the doctrine of selection, but the opponents of this theory sometimes seem to overlook the fact that, in the first place, it is not in the least necessary to assume that variations will be *slight*; they are often, on the contrary, in the case of specially plastic individuals, very extensive when these are subjected to a change of environment. And, in the second place, it is not necessary to suppose that any given species, and far less any individual, will vary equally in different directions round its average or mean. A very slight acquaintance with horticultural operations is enough to convince any one that certain races are specially plastic as regards one organ, whilst in others modification is most easily provoked in a different one. And selection, acting as it essentially does by eliminating those which conform less readily to the requirements of the environment, can hardly be dismissed, as M. Constantin dismisses it, as of relatively small importance in the evolution of species. But the difficulty really does exist if we only assume the possibility of slight variation ranged equally round a mean. In this case, of course, it is difficult (apart from isolation, physical or physiological) to see how a new species could be evolved at all when the chances of intercrossing are considered. But, as has been indicated, such a restriction is entirely gratuitous, and, furthermore, is contradicted by experience.

The facts adduced by the author, drawn from the studies of Schübeler and Bonnier, on the sudden evolution of spring- from autumn-wheat, hardly seem to help the case of the inheritable influence of the surroundings at all. For it is conceded that if autumn-wheat be sown in spring, a large percentage of the plants do not ripen fruit. Those that do succeed may, however, be supposed so to develop because their latent possibilities in this direction were greater than those possessed by their unsuccessful comrades. Next year, of course, the sowings obtained from the survivors will possess the same character for speedy growth and early maturity in a far larger average number, since the parents *all* had clearly a trend in the required direction. But it is misleading to speak of this as an inherited effect due to the impressed action of the environment, *i.e.* the inheritance of an acquired character, for it is clearly nothing more than the encouragement of possibilities which were latent before, and, but for the changed conditions, might never have been raised to the position of criteria of existence at all.

But this confusion between an outside moulding influence (*e.g.* mutilation) and the *evoking* from the plastic organism of a suitable response to the environment imposed by new conditions, is very wide-spread; and although the difference is in reality one altogether of kind, it is often in practice overlooked.

A good summary is given of some of the interesting results obtained by French investigators on crossing races and species, but some of the other chapters strike one as rather weak, *e.g.* those dealing with the action of gravity on plants. The account of aquatic plants is also somewhat disappointing, especially as the author has himself worked in this branch of the subject.

Nevertheless, the book is worth reading, bringing together as it does a considerable body of scattered facts which are lucidly arranged within a moderate number of pages.

J. B. F.

## THE NEWTONIAN POTENTIAL.

*Théorie du Potentiel Newtonien.* By H. Poincaré. Pp. 366. (Paris: Georges Carré and C. Naud, 1899.)

THE course of lectures given by Prof. Poincaré at the Sorbonne during the session of 1894–5 has, under the editorship of Dr. Édouard Leroy and M. Georges Vincent, assumed the form of a text-book on attractions and the theory of the potential.

The subject-matter naturally falls into two sections, one referring to special properties of potentials of linear, superficial and volume distributions, and the other dealing with Dirichlet's problem and its solution. It is rather a pity that this division was not adhered to in the arrangement of the text. Chapter vi., dealing with the potentials of magnetic shells, is quite out of place in the middle of Dirichlet's problem, and should logically have preceded the two previous chapters.

In opening what we have regarded as the first subject, M. Poincaré introduces concurrently with the Newtonian potential the logarithmic potential corresponding to the law of the inverse distance, which represents the two-dimensional potential of infinite cylindric distributions. The first chapter, which includes calculations of the potentials of rods, cylinders, spheres, and other simple forms, deals with potentials of bodies at external points. It contains a brief account of Legendre's coefficients. In passing to the interior of the attracting mass in Chapter ii., the question of the convergency of the integrals representing the potential and its derivatives naturally necessitates a brief digression on convergent integrals in general. Chapter iii. deals with potentials of linear and superficial distributions of matter, and naturally leads on to the misplaced Chapter vi., which treats at considerable length of "double layers" (*doubles couches*)—in other words, magnetic shells.

The second subject opens in Chapter v., where Dirichlet's problem is stated, the principal properties of Green's function are proved, and the equivalence of the two problems is established. In the next chapter Prof. Poincaré gives the solutions of Dirichlet's problem for a circle and a sphere, and deals with the properties of conjugate functions and conformal representation in two dimensions. Chapter vii. treats of the method of exhaustion (*balayage*), and the remaining eighty pages contain a fairly detailed account of Neumann's method and its extensions.

Lecture notes are rather apt to be deficient in explanation on points which have either been taken for granted by those who transcribed them, or have been incidentally explained in a conversational way by the lecturer. Any one not starting with a previous knowledge of the definition of the potential would hardly find M. Poincaré's opening very clear. In first "letting" $f_1'(r_1)$ be the attraction at distance $r_1$ and afterwards defining the potential as $-\Sigma f(r)$ it ought to be explicitly stated that $f_1'(r_1)$ is the derived function of the subsequently introduced function $f_1(r_1)$. Moreover, why should the constant of integration in $f_1(r_1)$ be taken as zero in the Newtonian and as $-m \log r_0$ in the logarithmic potential? A few additional words of explanation in such cases would often save readers from wasting time over unnecessary difficulties.

There are many problems which, although belonging to the subject proper of attractions and potential, are not included in the present volume. The potentials of ellipsoids are untouched, Lamé's ellipsoidal harmonics being dismissed with a mere reference. Then, again more might have been said about spherical harmonics. It will be seen, however, that M. Poincaré's lectures have reference to the general theory of the potential rather than to special problems, which find appropriate treatment elsewhere.

As an introduction to this theory dealing at some length with Dirichlet's and Neumann's developments, M. Poincaré's volume bids fair to be a useful addition to the library of college lecturers as well as of the more advanced class of mathematical students.

G. H. B.

## OUR BOOK SHELF.

*Faune de France—Mammifères.* By A. Aclogue. Pp. 84; Figs. 9. (Paris: Baillière.)

As compared with that of the British Isles, the mammalian fauna of France is much more extensive, comprising a number of Mediterranean types quite unknown among the former. It is therefore, altogether apart from patriotic considerations, well worthy of being separately monographed. This task has been undertaken by the author of the present little volume; and although in the main the very condensed descriptions given appear satisfactory so far as they go, we cannot but regret that the work was not written more on the lines of Bell's "British Quadrupeds."

The volume commences with an illustrated dissertation on the characteristics of, first, the Vertebrata and then of mammals; and in this part we notice that on p. 21 the author figures the skull of a bat as that of a mole, and also one of a porcupine as that of a second representative of the insectivorous order.

The illustrations are, indeed, very discreditable, the only passable ones being those borrowed from other works. In these days of cheap "process-blocks" it does seem inexcusable to issue caricatures like those in the present volume. The type, too, is extremely small.

The descriptions of the genera and species, although, as already said, very short, are sufficient to admit of their identification. Some of the terms used, such as (p. 73) "*Bosidi*"—the equivalent of *Bovidae*—sound, however, somewhat strange to English ears; and it may be added that the nomenclature generally is by no means altogether up to date. Moreover, even if it be considered advisable in a work of this nature to introduce the ordinary indigenous domesticated animals, such as sheep and oxen, there seems little to justify the inclusion of such a palpable foreigner as the guinea-pig.

The best we can say is to express the hope that the author may, before long, see his way to reissue what forms the rudiments of a very useful work on a scale more commensurate with the importance and interest of the subject.

R. L.

*Anatomical Diagrams for the use of Art Students.* By James M. Dunlop. Pp. 72. (London: George Bell and Sons, 1899.)

As to how much or how little knowledge of anatomy the art student should possess is a matter on which opinion is very much divided. Your youthful impressionist is apt to sneer at anatomy; as a rule, his contempt for the subject is revealed in the construction of the forms he represents. On the other hand, the more serious-minded and studious of the artistic fraternity, those who, by hard work and diligent study, are laying the foundations upon

which a true impressionism can alone be based, have found and do find the study of anatomy a help in their work.

That such knowledge may be abused is not surprising; the example of the unfortunate Haydon might serve as a warning. Yet there are plenty of instances in modern work in which this knowledge is duly restrained. Leighton had a keen appreciation of anatomical detail, and his bronze of an Athlete struggling with a python is likely to outlive most, if not all, his pictorial efforts as a work of art.

Books on so-called artistic anatomy, written usually by surgeons and anatomists having little or no knowledge of the requirements of artists, have, as a rule, been prepared by "boiling down" the technical treatises supplied to medical students. It is to Dr. Paul Richer that we are indebted for having dealt with the subject in an appreciative spirit; he approaches it, not merely from the standpoint of the anatomist, but from that of the artist as well. His method is to represent the figure in action in different poses, and submit a chart explanatory of the various structures on which the surface contours depend, having first, of course, supplied his readers with such information regarding the bones and muscles as is necessary to enable them to understand and appreciate the diagrams. It would be difficult to over-estimate the value of his book; its cost, however, places it beyond the reach of most students.

When an art-master produces an atlas of anatomical diagrams, we naturally expect to have fresh light thrown on the subject, together with a keener appreciation of the requirements of art students. We are not inclined to be too exacting with regard to the anatomical details if only we can get some further insight into their application to the study of the human figure.

In an interesting introduction to the present volume, Prof. Cleland, whose artistic sympathies are well known, makes use of the statement that the work occupies "ground which has not hitherto been taken up." With this opinion we cannot agree; for, as a matter of fact, the bulk of the illustrations in this atlas are reproductions, somewhat diagrammatically treated, of tracings or combined tracings of Richer's drawings. To these the author has had no hesitation in affixing his name without, so far as we can ascertain, once mentioning the source from which his figures are derived. The only features in the book which display any originality are the plates in which those parts of the skeleton having a direct relation to the surface contours are blocked in in distinctive colours. The absence of explanatory text, as well as the lack of reference to the contours of the figure in action, seem to us to minimise its value as a textbook to be placed in the hands of students. As diagrammatic reproductions of Richer's figures, the plates in this atlas may not be without value. We confess, however, to a preference for the originals.

*Chemistry for Continuation Schools.* By R. L. Taylor. Pp. 52. (Manchester: Thomas Wyatt, 1899.)

THIS little book, like many others which have appeared during the past few years, should assist the progress of rational methods of teaching elementary chemistry. It consists of a series of nearly a hundred simple experiments to be performed by or for pupils commencing the study of chemistry. The subjects illustrated by the experiments are elements and compounds, chemistry of the air, water, acids and alkalis, carbon and carbon dioxide. Pupils who perform the experiments will obtain a sound knowledge of the nature of chemical changes, and of the properties of some common substances.

Fig. 3, illustrating the preparation and collection of oxygen from potassium chlorate and manganese dioxide, shows a liquid in the flask instead of the oxygen mixture.

## LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

### Blue Ray[1] of Sunrise over Mont Blanc.

LOOKING out at 5 o'clock this morning from a balcony of this hotel, 1545 metres above sea-level, and about 68 kilometres W. 18° S. from Mont Blanc, I had a magnificent view of Alpine ranges of Switzerland, Savoy, and Dauphiné; perfectly clear and sharp on the morning twilight sky. This promised me an opportunity for which I had been waiting five or six years; to see the earliest instantaneous light through very clear air, and find whether it was perceptibly blue. I therefore resolved to watch an hour till sunrise, and was amply rewarded by all the splendours I saw. Having only vague knowledge of the orientation of the hotel, I could not at first judge whereabouts the sun would rise; but in the course of half an hour rosy tints on each side of the place of strongest twilight showed me that it would be visible from the balcony; and I was helped to this conclusion by Haidinger's brushes when the illumination of the air at greater altitudes by a brilliant half-moon nearly overhead, was overpowered by sunlight streaming upwards from beyond the mountains. A little later, beams of sunlight and shadows of distant mountains converged clearly to a point deep under the very summit of Mont Blanc. In the course of five or ten minutes I was able to watch the point of convergence travelling obliquely upwards till in an instant I saw a blue light against the sky on the southern profile of Mont Blanc; which, in less than the one-twentieth of a second became dazzlingly white, like a brilliant electric arc-light. I had no dark glass at hand, so I could not any longer watch the rising sun.

KELVIN.

August 27.

### A Fold Making Apparatus for Lecture Purposes.

I HAVE found the piece of apparatus which I am about to describe so effective for lecture experiments, that I venture to think that others engaged in geological teaching may be glad to possess details as to its construction and mode of operation.

The machine (Fig. 1) consists of two parallel wooden rollers, about 3 feet apart. Each is about 12 inches long and 4 inches

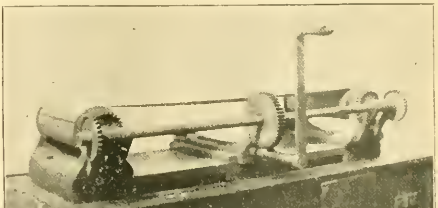

FIG. 1.

in diameter. A shaft at right angles to their length turns the two rollers in opposite directions by means of toothed bevel wheels, the shaft itself being driven by a worm wheel and worm, the latter being actuated directly by the handle. One turn of the handle only causes $\frac{1}{4^0}$ turn of the shaft and rollers, so that a very slow motion can be imparted to the latter. A sheet of

[1] The "Rayon Vert" of Jules Verne is the corresponding phenomenon at sunset; which I first saw about six years ago.

india-rubber about $\frac{1}{2}$-inch thick, firmly attached by a slot and screwed bar to each roller, completes the arrangement.

The rollers being wound through about one entire revolution, and the india-rubber being thus stretched tight, layers of cloth, clay, paste or other giving material, are laid upon it. The handle is then turned in the reverse direction, and the india-rubber gradually released. Folds are in this way shown slowly growing—the broad elastic band simulating the contraction of a portion of the earth's crust. In Figs. 2 and 3, cloths are seen

FIG. 2.

FIG 3.

folded thus—first, without superincumbent weight, and second, with a weight of 30 lbs.

That the larger folds are those generated at the surface, and the smaller and more numerous those produced under pressure (*i.e.* at great depths), is here made evident.

By substituting blocks of stone or wood for ordinary weights above the cloths (Fig. 4) and repeating the experiment, some of the relations between folding and faulting are clearly shown.

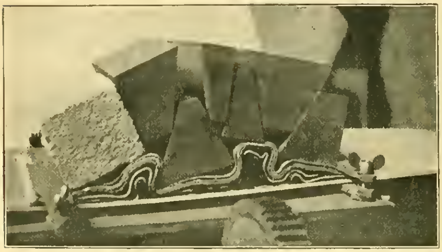

FIG. 4.

If clay be used instead of cloths, all the results of Favre's well-known experiments (*Arch. d. Sciences Phys. et Nat.*, 1878, and also NATURE), and many of those described by Cadell, Bailey Willis and others, can be obtained, and with the exercise of a little ingenuity it is easy to vary the experiments so as to reproduce a large number of the fold-forms known, and to illustrate their consequences—thrusts, faults, &c.

This machine was made for me in 1880 by the late Mr. C. D. Austen, of Newcastle-upon-Tyne, from my designs.

G. A. LEBOUR.

The Durham College of Science, Newcastle-upon-Tyne, August 18.

## Scoring at Rifle Matches.

IN his letter to NATURE of August 17, Mr. Mallock appears to assume that there is such a thing as abstract "accuracy" in estimating the value of a marksman's score. The method in use at Bisley is, as I understand him, to be regarded as a rough approximation to the accurate method, whether the best available approximation or not. Is it not rather the case that the standard of accuracy is itself arbitrary, and what the authorities at Bisley have established is not an approximation to an ideal standard, but is to be regarded as a real standard of excellence?

In result Mr. Mallock's "accurate" method is this: in his notation any two scores for which $R^2+\rho^2$ is the same are of equal merit, or that one for which $R^2+\rho^2$ has the least value is the best score. Now, if "$a$" be the distance of any shot mark from the bull's-eye, $n$ the number of shots, $R^2+\rho^2=\Sigma a^2/n$. Mr. Mallock's standard, then, is that the best score is that for which the sum of the squares of the distances from the bull's-eye is minimum. I see no reason why this method should be regarded as accurate *par excellence*, except the analogy of the method of least squares. But the analogy is misleading.

Where the method of least squares is applicable, the object is to find the most advantageous value of an unknown quantity to be deduced from a number of observations. An accurate value of the quantity does exist. And of two or more results deduced from the observations, that which is nearer to the accurate value is always better than one more remote, however near to the truth either may be.

In rifle shooting, on the other hand, there is generally some finite space—*e.g.* the port-hole of an enemy's ironclad, such that all shots which pass through it are of practically equal value, and all shots which do not pass through it are of little or no value.

This is much more accurately represented by the Bisley method than by the method which Mr. Mallock would substitute for it.

S. H. BURBURY.

THE only remark I should wish to make on Mr. Burbury's letter is that every shot on the target is truly the record of an observation, and that there is every reason to treat these records as far as is practicable by the methods which apply in obtaining the best means of a number of observations. Of course, it is only in the case of "centre of target" competitions the "$R^2+\rho^2$ a minimum" test applies. Prizes might well be given for close grouping, with a penalty depending on the mean distance of the group from the centre of the target.

August 22. A. MALLOCK.

## Spectrum Series.

SIR NORMAN LOCKYER'S lectures on "Spectrum Series" seem to show very clearly the important fact that there is a close connection between the valency of an element and the lines in its spectrum.

The connection indicated is as follows:—

Nonvalent elements yield spectra with single lines.

Monovalents yield doubles.

Divalents yield triplets.

On turning to the list given in NATURE (vol. lx. p. 370), it will be seen that helium, by yielding doubles as well as singles, and cobalt, by yielding doubles only, are practically the only discordant cases in Sir Norman Lockyer's list, since aluminium and indium are trivalents, and their anomalous behaviour in yielding doubles only can perhaps be explained.

August 26. W. SEDGWICK.

## Magnetic "Lines of Force."

IN some text-books and by some lecturers (*e.g.* Prof. A. Gray, as reported in NATURE of August 17, p. 379), the lines of magnetic force are said to be the curves along which iron filings are marshalled when sifted over a piece of card laid over a horizontally placed magnet.

Surely this is hardly correct. The true lines of magnetic force must be represented, like those of all other radiant forces, by radiating straight lines drawn through the points of action of the resultants of all the forces residing in the individual molecules of a given magnet (such points, though varying in position with the position of a magnetic body in the field, being often referred to as fixed "poles").

The symmetrical figures traced out by iron filings merely show, of course, the directions in which a line joining the poles of a very short magnet will lie in different parts of a magnetic field, under the influence of the true lines of force. E. R. P.

August 29.

## Critical Pressure.—A Suggested New Definition.

THE critical pressure of a substance is commonly defined as "the least pressure that will suffice to reduce that substance from the gaseous to the liquid state when at its critical temperature." But this definition contemplates the matter solely from the standpoint of what occurs at the critical temperature, and I think it

would sometimes be an advantage to have one presenting a broader view and making no reference to any specific temperature, just as the ordinary definition of critical temperature makes no reference to any specific pressure.

Now, if in a *pv* diagram we draw the curve formed by the liquid and vapour lines, the indicator points corresponding to the "mixed state" (*i.e.* part vapour and part liquid, each more or less distinctly discernible) lie wholly within the region bounded by this curve and the axis of volume; also the ordinate of the highest point of this curve—where, of course, the tangent is horizontal—corresponds to the critical pressure, and the "critopiestic" or critical pressure line is the said horizontal tangent.

All horizontal lines below the critopiestic intersect the region corresponding to the "mixed state," while those above do not, thus showing that at pressures below the critical the substance changes from gas to liquid, or *vice-versa*, by the *ordinary* process of condensation or evaporation, *i.e.* by passage through the mixed state, while above that pressure this process does not take place, but the change occurs by continuous and imperceptible transition.

Of course all this accords with experiment, as is pointed out in several, though by no means all, the standard text-books. Thus on p. 123 of the new edition of Clerk Maxwell's "Theory of Heat," revised by Lord Rayleigh, we read:—"If we begin with carbonic acid gas at 50° F. we may first heat it till its temperature is above the critical, 88° F. We then gradually increase the pressure to, say, 100 atmospheres. During this process no sign of liquefaction occurs. *Finally we cool the substance still under a pressure of* 100 *atmospheres to* 50° *F. During this process no sudden change of state can be observed, but carbonic acid at* 50° *F. and under a pressure of* 100 *atmospheres has all the properties of a liquid . . . by this process we have caused the substance to pass from an undoubtedly gaseous to an undoubtedly liquid state without at any time undergoing an abrupt change similar to ordinary liquefaction.*"

Again, on p. 206 of the "Text-Book of Physics," by Mr. Alfred Daniell, we find:—"If $CO_2$ gas be exposed to a temperature above 30°·92 C. and be subjected to any pressure above 73 atmospheres, it will still be a gas: *allow it to cool, the pressure being kept up, and it will be a liquid after it passes* 30°·92 *C., and yet the transition is unobservable.*"

I therefore propose to define the critical pressure of a substance as "that pressure above which it is impossible to make the substance undergo the *ordinary* process of condensation (or evaporation)"—or if greater amplification is needed as "that pressure above which an appropriate alteration of temperature causes the substance to pass from the gaseous to the liquid state or *vice-versa, by a process of continuous and imperceptible transition*, and not, as happens below that pressure, by *passage through the mixed state.*"

This definition I have given in my recently published book, "Physics: Experimental and Theoretical," but the *Times* reviewer, in a paragraph in that paper of July 29, characterises it as "mere nonsense."

I shall be greatly obliged if you will publish this letter, together with your opinion on the validity of my definition. Perhaps also some of your readers may favour me with an expression of their views. R. H. JUDE.

Newcastle-upon-Tyne, August 2.

### Maternal Devotion of Spiders.

ON removing some virgin cork from the wall of a conservatory a short time ago, I was much struck with the way in which a small black female spider clung to her two egg-bags, despite the fact that the piece of cork to which she was clinging had been thrown roughly to the ground. When the cork was about to be replaced on the wall, it became necessary to turn the spider adrift, in order to prevent her being crushed. But although the cork was shaken, she declined to budge, and retained a tight hold upon her precious bags. Knowing how fully alive to danger the spider race is in general, I thought that this remarkable instance of devotion to maternal promptings on the part of a naturally sensitive creature ought not to be disregarded. I accordingly removed the mother very carefully, and placed her on some rockwork, where I noticed she seemed to be very uneasy, moving restlessly about as if searching for something. I then took the egg-bags and placed them beside her. As I expected, she seemingly failed to recognise them, or at least manifested a repugnance to them, and ran away for a little distance. Subsequently, however, she returned, and proceeded to examine the bags with scrupulous care by means of her palpi; and evidently satisfied with this scrutiny that they were really her own cherished property, she commenced to spin a web about them to secure them in their place.

Rennie has described experiments with the females of certain spiders which carry about their egg-bags attached to their bodies. When one of these spiders was molested, and its bag dragged with a stick, the mother seemed to lose all sense of personal danger in her anxiety for her unhatched offspring, and fought vigorously to retain her precious egg-bag. When forcibly deprived of the bag, she manifested great distress, and commenced a search for it, and, not finding it, she refused to leave the spot, seeming to be quite indifferent as to her fate. The curious part of the story is that when the egg-bag was finally restored to her, she refused to touch it, being apparently quite unable to recognise her property. In another case the spider regained possession of the bag as it was being withdrawn, and immediately refixed it in its former position.

My spider apparently recognised her egg-bags without much difficulty, and, furthermore, seemed to be alive to the danger to which they were exposed in their new situation by her act of spinning a protecting web without delay. When evening arrived, I observed that she had drawn the bags close up under a sheltering leaf, and was guarding them closely, having placed herself between them. FRANCIS J. ROWBOTHAM.

August 23.

## THE CAMBRIDGE ANTHROPOLOGICAL EXPEDITION TO TORRES STRAITS AND SARAWAK.

THE main object of the expedition was to verify and supplement the anthropological observations that I made in Torres Straits in 1888–89, with the view of the publication of a monograph dealing with the anthropology of the islanders using that term in its widest sense. A few months before leaving I received such a pressing and enthusiastic invitation from Mr. Charles Hose for the expedition to visit the Baram district of Sarawak, that I felt constrained to extend the scope of our work by accepting his tempting offer. The party consisted of Dr. W. H. R. Rivers, Messrs. C. S. Myers, W. McDougall, S. H. Ray, A. Wilkin, C. G. Seligmann, and myself.

The Torres Straits islanders are Papuans, and as they inhabit the remains of the old land communication between Australia and New Guinea it was important that they should be thoroughly studied before it was too late. The islanders have been more or less under mission instruction since 1872, and some time before then the pearl-shelling industry had commenced. Owing to the varied influences of the white man, modification was bound to take place rapidly, and unfortunately in most islands more or less extensive depopulation has also occurred. There are two distinct tribes in the archipelago—the eastern tribe inhabits the Murray Islands, Erub (Darnley Island) and Uga, and the western tribe the remaining islands. The latter people have been most under the influence of white men, scarcely a pure-blooded native exists in Erub, but the Murray Islands, on account of their remoteness and the difficulties in reaching them owing to numerous coral reefs, have been less visited. As Mer, the chief island of this group is very fertile, and has a population of some 450 people, it appeared to be the best centre for our work.

We reached Mer on May 6, 1898, and took possession of the disused mission residence, which we speedily converted into anthropological, psychological and photographic laboratories. Here we measured 63 men, 5 women, 30 boys, and 22 girls. The average height of the men is 1·653 m. (5 ft. 5 in.); their cephalic index is 77·5. Although reference is made here only to the cephalic index and the height, I may state that we usually made

twenty-two measurements on the subjects in Torres Straits, New Guinea, and Borneo, besides a number of observations on the skin, hair, eyes, face, &c.

Psychological observations were made in the Murray Islands on about 150 individuals. Among the subjects investigated were visual acuity, delicacy of colour sense, colour blindness, binocular vision and visual perception of space; acuity and range of hearing, appreciation of musical intervals; tactile acuity and sensibility to pain, and discrimination of weight; acuity of smell; simple reaction time to auditory and visual stimuli and choice reaction time; estimation of intervals of time; the influence of various mental states on blood pressure; and the influence of fatigue and practice on the capacity for mental work. By means of colour matches, quantitative records were also taken of the colour of the skin of the islanders.

We were fortunate to find two or three old men who were able to tell us about the old customs and ceremonies. A good deal of time was spent in elucidating the long since abandoned sacred Malu ceremonies which were held in connection with the initiation of the youths; the previous account[1] can now be considerably augmented. Notes were made of various other ceremonies, and whenever possible the ancient sacred songs were recorded on the phonograph. A large collection was made of sacred stones, including stones about which there is a legend, sorcery stones, fishing and garden charms, rain and fire charms. Numerous legends were also collected, and many of the sites and stones connected with them were photographed by Mr. Wilkin.

The old oracle known as "*Tomog zogo*," which consisted of a group of large shells on stones, to represent each group of houses on the island, and a shell "house" for the *zogo*, was plotted, and the former method of divination was demonstrated to us. One or two members of the party learnt the constellations on the voyage out; this enabled us to map some of the native star groups. Attention was also paid to children's games, and a system of nomenclature was devised which enabled us to record with accuracy the complicated manipulation in the making of the ingenious string puzzles or "cat's-cradle." Examples of the past and present handicrafts of the people were collected. The construction of the language was carefully studied by Mr. Ray, and the previously published vocabulary increased. The native diseases and their cures were studied with the cognate charms and magic.

Messrs. Ray, Seligmann, Wilkin and myself paid a brief visit to the mainland of New Guinea, and visits were paid to Rabao (Yule Island) and to several villages of the Mekeo district. Twenty-eight men were measured: average height, 1·610 m. (5 ft. 3½ in.); cephalic index, 80. As the decorative art of the Mekeo district has not been described hitherto, numerous specimens of lime-gourds, tobacco-pipes, and painted tapa were collected.

A short stay was made at Port Moresby, where a number of photographs were taken to illustrate the manufacture of pottery, and a visit was paid to the Taburi tribe that lives behind Mount Warirata. Nine mountaineers from the centre of the Peninsula were measured: height, 1·607 m. (5 ft. 3¼ in.); cephalic index, 80·8, as well as fourteen Koiari from the hilly country: height, 1·600 m. (5 ft. 3 in.); cephalic index, 75·5; and six Koitapu of Port Moresby: height, 1·603 m. (5 ft. 3 in.); cephalic index, 77·1. A study of the Koitapu language was made, which proved that it, like the people themselves, does not belong to the Motu stock. These three groups differ in several respects from the Motu communities that inhabit most of the coast villages from Delena to Aroma; for example, they commonly wear hair on the face, and the hair is almost invariably frizzly.

A few days were spent at Bulaa (Hula), where we were struck by the relative prevalence of curly and even of wavy hair, and the general lighter colour of the skin: height, 1·663 m. (5 ft. 5½ in.); cephalic index, 82·5. I intend on a future occasion to discuss the physical characters of the Papuans at some length when I have had time to tabulate out our results, and to compare them with those of other workers. At present it appears to me that a short, slightly brachycephalic people live among the mountains, and a similar short mesaticephalic (with a distinct tendency towards dolichocephalism) folk live nearer the coast. It is the latter people who have been repressed by the taller brachycephals of the coast, whose foreign blood is shown by their lighter skin and a marked frequency of curly or even wavy hair. The mountaineers are in no sense a pygmy people, and are not directly related to the Aëtas; they frequently harass and conquer the dolichocephals.

Messrs. Ray, Wilkin and myself returned to Murray Island on July 20, Mr. Seligmann remaining behind to see more of the country. Dr. Rivers and Messrs. Myers and McDougall had made a large number of interesting psychological observations during our absence. The two latter left for Borneo on August 24.

On September 8 we left Murray Island and arrived at Saguane at the southern end of Kiwai Island in the delta of the Fly River on the 11th. A visit was paid to Iasa, which contains sixteen long houses, each of which is inhabited by members of one totemistic clan, and eleven natives were measured: height, 1·602 m. (5 ft. 3 in); cephalic index, 80·3. Mr. Seligmann rejoined us here.

Our next destination was Mabuiag, which we reached on September 17, and had five weeks of good work recording old customs, measuring natives, studying language and experimental psychology. In Mabuiag and Kiwai fewer psychological observations could be made, owing to the fact that most of the apparatus had to be taken on to Borneo, but observations on visual acuity, colour vision, &c., were made on over 100 individuals, many of whom, however, were not natives of these islands. Thirty-three men were measured: height, 1·648 m. (5 ft. 4¾ in.); the average cephalic index is 81·1. Although they belong to the same race, and are similar in many respects, there is a noticeable difference between the eastern and western tribe of Torres Straits. Most of their former ceremonies and many of their customs were dissimilar, the languages are quite distinct, and on the whole the western folk are more intelligent. The very slight difference in the stature may be due to the more abundant food of Murray Island, whereas that of the head form is of greater significance. The difference between an average index of 77 and 81 may not appear large, but there is a distinct difference in the form of the skulls in general from the two islands. I am inclined to believe that the Murray Islanders belong to that dolichocephalic stock which certainly occurs on the mainland of New Guinea in the region known under the general name of Daudai, and which appears to have been pushed back by a somewhat brachycephalic people. Murray Island was unaffected by this movement, but the western islands have not escaped it. I have no desire to push craniological facts too far, and I propose testing this hypothesis elsewhere by cultural evidence. Several writers have expressed an opinion that the natives of Prince of Wales Island and the neighbouring islands are Australians with a strong Papuan mixture. I regard them as Papuans, with a very slight (if any) Australian mixture.

The most interesting of our sociological investigations of the Western tribe were those on totemism, maturity customs for men and women, and the beginnings of hero-worship as exemplified in the legend and cult of Kwoiam, the national hero of Mabuiag. Here, as at Mer, Dr.

[1] *Internationales Archiv für Ethnographie* (vi., 1893, p. 140).

Rivers traced as far as possible the genealogy and relationships of every person on the island. This somewhat laborious work has proved a most valuable method of anthropological research, which, so far as I am aware, has not been attempted before for a whole community. The value of this method consists in the large number of accurate sociological data that are accumulated.

Short visits were paid to other of the western islands of the Straits in which ethnographical facts and specimens were collected.

At Mabuiag, and later at Thursday Island, we had an opportunity of studying some North Queensland natives, and the contrast, both mentally and physically, between them and the islanders was obvious. The average height of seventeen Queenslanders was 1·626 m. (5 ft. 4 in.), and their average cephalic index was 74·5.

We finally left Torres Straits on November 15, 1898.

Messrs. Ray, Seligmann and myself reached Kuching on December 12, where we had to remain until January 4; Mr. Ray occupied the time in learning Malay, and I laid the foundations of a study of the decorative art of Sarawak by utilising the collections in the most excellent museum which the Rajah has so wisely and liberally endowed. The foundation of the ethnographical collections was the very valuable Brooke Low collection, which the Rajah bought in England and reshipped to its native land. This has been added to from time to time, and, although there is a good deal to be done before all the handicrafts and arts of the natives of Sarawak are fully illustrated, the museum contains the best and most instructive collection of Sarawak ethnography extant. The fauna of Sarawak is also most fully represented, and the value of the collections is daily increased by the well-directed labours of the curator, Mr. R. Shelford.

During the north-east monsoon it is impossible for a steamer to cross the bar at Baram Mouth, and this necessitated our proceeding to Limbang, where we had to remain a few days whilst messengers were sent to Mr. Hose. We then had to journey some 200 miles in boats up the Limbang, Madalam and Trikan rivers, and after walking across the watershed at the foot of Mount Mulu we descended the Malinau, Tutau and Baram, arriving at Marudi (Claudetown) on January 28, where we rejoined Mr. McDougall, Mr. Myers having been obliged to return home a few days previously. On February 6 Mr. Hose took Messrs. Ray, MacDougall and myself an up-river trip, Mr. Seligmann was busy studying *upoh* (*upas*), *tuba* and other poisons; later he stayed some time among the up river Kayans. We went over 200 miles up the rivers Baram, Tinjar, Dapoi and Lobong, and saw many interesting scenes, and gained further experience of the jungle vegetation of a typical tropical land.

At Long Puah we witnessed the ceremony of moving the skulls into a new house from the hut in which they had been temporarily lodged, and then we participated in the ceremony of naming the first-born son of the chief. On the same occasion peace was made between two hostile tribes, and the covenant was ratified in the usual manner by "speaking" to some pigs, that were then killed and their livers inspected for augury. In one village we saw a Punan medicine man exorcise fever from a white man by means of incantations and obvious thaumaturgics. We gained fair insight into the mode of life and beliefs of several tribes of the interior; we made collections to illustrate their handicrafts and decorative art: numerous photographs were taken, which unfortunately have not proved a success owing partly to climatic conditions. Physical measurements were made of a large number of natives, and vocabularies collected. We also had an excellent object-lesson in the paternal administration of native affairs that is the keynote of the Sarawak system of government.

It was on this trip that I discovered a stone implement in a native house, close by the usual skulls and associated with other sacred objects. After great difficulty Mr. Hose succeeded in procuring it, and later he secured several other specimens of varied types. With the exception of a specimen in the museum at Oxford of a very different type from any we obtained, and one recently acquired by the Sarawak Museum, these are the only authentic stone implements known from Borneo. Mr. McDougall and I paid a hurried visit to Mount Dulit, but nothing of interest was collected.

Later on Mr. Hose took me to visit Tama Bulan, the great Kenyah Penghulu, who lives on the Pata River. Messrs. Myers and McDougall had previously visited him.

Towards the end of our stay in Baram we were present at a great peace-making, when quite 6000 natives assembled from all parts of the Baram district, and even from beyond its borders. We thus had an unique opportunity of seeing representatives of nearly every important tribe of the Raj. Amongst other incidents we witnessed a canoe race in which about one thousand men competed, and participated in an attempt to *tuba*-poison a large lake in which over two thousand men were engaged.

We have now in Cambridge specimens to fairly well illustrate the arts and crafts of the natives of Sarawak. Mr. Ray obtained material for grammars of the two dialects spoken respectively by the Land Dayaks and by the Sea Dayaks, as well as notes upon several other languages. Vocabularies of over 200 words were obtained in forty-six dialects spoken by various tribes of Sarawak. Mr. Myers made numerous psychological observations. Mr. Seligmann studied native medicine, &c. Mr. McDougall paid special attention to the question of the relations of men to animals and plants in Borneo, and helped me with the measurements and physical observations of the natives. In all we measured some 276 natives, the bulk of whom are mesaticephalic or slightly brachycephalic. The following are some of the approximate average indices (the numbers in brackets refer to the number of each tribe that were measured):—Maloh (7)—probably an immigrant people from Java—76; Barawan (17), 77·5; Kalabit (10), 78; Kenyah (103), 79—of these the Sibops (5) have the lowest index with 75·5, which gradually rises through the Malangs (20), 76·5, Tabalos (3), 77·5, Madangs (6), 78, Long Pokun (19) and Lirong (15), 79·5, Long Dallo (12), 80·5, Apoh (9), 82, to the Long Sinong Kenyahs (5), with an index of 83·5—this does not appear to be a very homogeneous group; Kayan (22), 80; Long Kiput (9), 80·5; Punan (22), 81; Sea Dayaks (53), 83; Malanaus (7), 85·5; Brunei-Malay (1), 85·5. We have not yet had time to study the skulls we brought away. I had an opportunity, however, of measuring five Murut skulls at Limbang, which had an average index of 75· (extremes 73–77·5). It is thus evident that there is a dolichocephalic element in Borneo which may be identical with the Indonesians as defined by de Quatrefages and Hamy in "Crania Ethnica." There is also a low brachycephalic element found among the up-river Kenyahs (Long Sinong, Apoh, and Long Dallo), Punans, and to a less extent among the Kayans. The Sea Dayaks are not an indigenous population; they probably constituted the advance wave of a later Malay migration. The Malanaus are Mohammedans greatly influenced by Malays, and who very frequently artificially deform the heads of their babies, so their relatively high index of 85·5 may be neglected. Although the Punan cephalic index (81) is close to that of the Sea Dayaks (83), the slender pale-coloured forest-dweller is physically very different from the short, sturdy, dark-skinned, low-country agriculturist. We were fortunate in coming across several groups of Punans, a nomadic jungle folk who are certainly one of the most primitive people in Borneo, and who may, perhaps, be the true autocthones of the country, for there is no

authoritative evidence for the existence of Negritos in Borneo.

The fascinating promises of Mr. Hose when he sent me his invitation to visit him were amply fulfilled so far as time permitted, and we have to thank him for a most enjoyable and instructive visit. Mr. Charles Hose is well known as a highly successful and enthusiastic naturalist. He has made collections in all departments of the land fauna of Sarawak, and he has monographed the mammals and the birds. His geographical explorations are also well recognised; but it is not generally known that he has a most minute and extensive knowledge of all that pertains to the numerous and varied natives that have been entrusted to his sympathetic care. I have seen piles of immensely valuable ethnographical manuscript which we sincerely hope will be suitably and speedily published. Not only has Mr. Hose from time to time presented his old University with numerous zoological specimens, but he has entrusted to me an extensive and very valuable collection of ethnographic specimens which he has given to the University of Cambridge. In addition he has presented the unique collection of stone implements and a large collection of human crania, each skull being labelled with its tribe and provenance.

I shall endeavour on another occasion to do justice to Mr. Hose's success as an administrator. What we were able to accomplish was largely due to those personal qualities of a ruler which awaken a feeling of affection and loyalty in the natives.

The Cambridge University Press will publish the scientific results of the Expedition in due course as a series of memoirs which will be obtainable separately. The volume on experimental psychology will be written by Dr. Rivers and Messrs. Myers and McDougall, with some supplementary observations on the natives of the mainland of New Guinea by Mr. Seligmann. Mr. Ray has ample matter for a volume on linguistics.

The linguistic results of the Expedition were on the whole very satisfactory. Materials were obtained for complete grammars of the two Torres Straits languages, and the vocabularies were revised. In New Guinea the Melanesian languages around Hood Bay were studied, as well as those of Rabao (Yule Island) and the adjacent mainland. In New Guinea also material was obtained to elucidate the somewhat complex structure of the Papuan languages of the Koitapu in the Port Moresby district, of the Cloudy Bay peoples, and of the Kiwai and Mowatta tribes in the Fly Delta. No grammar of any of these languages has hitherto been written. The materials obtained in Borneo for grammars of the two dialects spoken by the Land Dayaks and Sea Dayaks, and vocabularies obtained in forty-six dialects spoken by various tribes of Sarawak have already been referred to.

The physical anthropology of Torres Straits and New Guinea will mainly be worked out by myself, but Mr. Seligmann has some additional measurements from the mainland of New Guinea. Dr. Rivers will publish and expound his statistical inquiries. Mr. Myers is making a comparative study of native music. Mr. Seligmann has studied native medicines and charms, and has made various ethnological observations of some interest. Mr. Wilkin has made notes on native houses in New Guinea. The religious ceremonies, legends, and general ethnology will be treated by various members of the Expedition. Mr. Wilkin took a large number of excellent photographs in Torres Straits and New Guinea, which will be drawn upon for illustrative purposes. As there is no room for them in the present Museum of Archæology and Ethnology, the extensive collections are deposited temporarily in a couple of small houses in Cambridge, where, unfortunately, they run risk of deterioration.

ALFRED C. HADDON.

## *WHY PEOPLE GO TO SPAS.*

ANY observer who has the curiosity to pass in review the modern methods of medical treatment cannot fail to be struck by the increasing amount of attention which is being paid at the present time, both by the laity and the profession, to the spa treatment of disease. The fact that many thousands of patients flock annually to the different health resorts to seek relief from their ills, and the idea which prevails among a large section of the educated public, chiefly the well-to-do classes, that their existence is not complete without a yearly visit to one or other of the many spas, either at home or abroad, and that for their bodily well-being an annual "cure" is necessary, are phenomena which call for comment and demand explanation. The practice is by no means of recent growth, for it finds its origin in the almost universal belief, prevalent in ancient times, in the efficacy of natural mineral waters and baths in the cure of disease. Many instances of this might be quoted. The waters of Spa in Belgium were celebrated in the time of Livy; the Romans built Bath in England, and fully recognised the value of its springs; and they in turn derived their fondness for bathing from the Greeks. There is not wanting evidence to show that more ancient civilisations appreciated in a rude way the benefits to be obtained in this direction from the resources of nature. Throughout the middle ages the same belief was held, and many were the pilgrimages to the various springs then known. In the present day the same idea, shorn of much of the superstition that formerly clung to it, still prevails, and each watering place claims annually its numerous devotees. Not only among the laity is the assurance of the therapeutic value of natural mineral waters and baths firmly rooted, though doubtless there still remains a substratum of lingering superstition as a part foundation of that assurance, but also by the medical fraternity their utility is accepted, as is witnessed by the freedom with which their patients are sent to take the waters of this or that spring. In the minds of the latter, however, superstition has been replaced by knowledge, and they are well assured that such treatment has a definite and real value.

It becomes, then, a matter of interest to seek answers to the following questions: Whether, in the light of modern knowledge and research there is a solid foundation in fact for the faith that is placed by patients and their doctors in the utility of bathing and water-drinking; whether such measures possess any advantages over treatment by ordinary medicinal means; whether the lines of treatment followed at spas cannot be carried out equally well at the patient's home, and the necessity for a perhaps inconvenient visit to a watering place thereby be obviated; and, lastly, whether equal facilities for such treatment, and results equally good, are not obtainable in this country as at similar places on the continent?

Up to comparatively recent times the use of waters and baths in the cure of disease was purely empirical. Through long experience and repeated trial it came gradually to be ascertained that certain waters were beneficial in certain cases, and certain kinds of baths produced certain effects; wherefrom was elaborated a system of spa treatment on more or less rule of thumb principles. The exact nature of the action of these agents, the physiological effects they produced and the pathological conditions they influenced were ill-understood; the rationale, in short, of the treatment was wanting. Of late years, however, a large amount of sound scientific work has been done in this department of medicine. The action of mineral waters and baths has been made the subject of definite experiment and the results obtained applied to the perfection and extension of the methods; and thereby this branch of therapeutics, which

formerly afforded tempting opportunities for scornful criticism on the part of the more advanced members of the profession, has now been placed on a firm scientific basis, and the ancient faith in it fully justified.

In this as in many kindred subjects the lead was taken by Germany, and as the result of much painstaking research a large amount of literature has appeared relating to the various spas in that country. Latterly the home watering places, such as Bath, Buxton, Droitwich, Harrogate, Leamington, Llandrindrod, Strathpeffer and others, have been brought more prominently before the notice of medical men, and through them to the public, by reason of similar research work conducted on scientific lines into the nature of the action of their respective waters and baths, by which their claims to equality with, if not superiority over, many of the continental resorts have been abundantly demonstrated. To illustrate this let us take Harrogate as an example, as possessing the greatest number and most varied assortment of mineral springs, and the most complete bathing establishment in this country, if not in Europe, and consider it with regard to its waters and baths. The former, some eighty in number, may be classified into certain groups of saline-sulphur waters, alkaline-sulphur waters, pure sulphur waters, saline-

F 1.—Entrance-hall and pump-room at the Royal Baths, Harrogate.

chalybeate waters, and pure chalybeates, each group embracing several members presenting fine gradations in quality and strength. The most important of these are set apart for drinking purposes; the others being collected, stored, and used for bathing. Long experience and trial of the waters has indicated the class of diseases in which they may be expected to prove beneficial, either individually or in combination, and these fall somewhat definitely into the following main groups, which, however, by no means include all cases which may derive benefit: disorders of the liver, functional or organic; cases of gout in its many manifestations; cases of rheumatism and so-called rheumatic gout; and cases of skin disease. The results obtained have been good, though based upon empirical knowledge, and a considerable reputation has been built up. In recent years, however, this has been strengthened by experimental work which has been carried out to determine the *modus operandi* of many of the waters, and the results of these researches have not merely corroborated in the main empirical practice, and furnished reasons for it, but have indicated new directions in which these agents may be advantageously employed. For example, the Old Sulphur Spring, the most valuable possession of Harrogate, has long been used in the past as a stimulant to the liver in sluggish or congested conditions of that organ. Recent research has shown by experiment on man and on animals that administration of this water definitely increases the flow of bile, as to rapidity, quantity, and the amount of solid constituents. And a further indication of increased activity of the liver is proved by an increase in

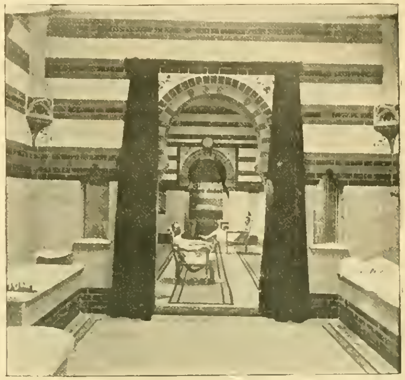

FIG. 2.—Interior of the Turkish Bath.

the amount of urea eliminated from the body. It has been used largely as a valuable remedy in gout, a part explanation of which is furnished by the diminished production of uric acid, which experiment shows to be one of the effects of this water. It has a well-marked effect on the blood in diluting it and diminishing slightly the amount of hæmoglobin, which explains its frequent use in plethoric conditions. The milder sulphur waters have

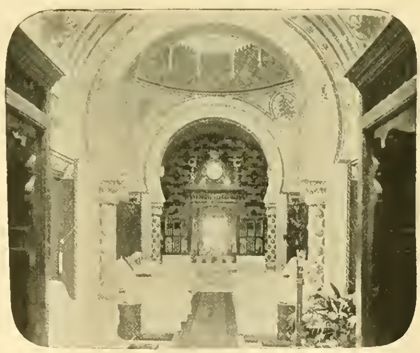

FIG. 3.—Cooling room of Turkish Bath.

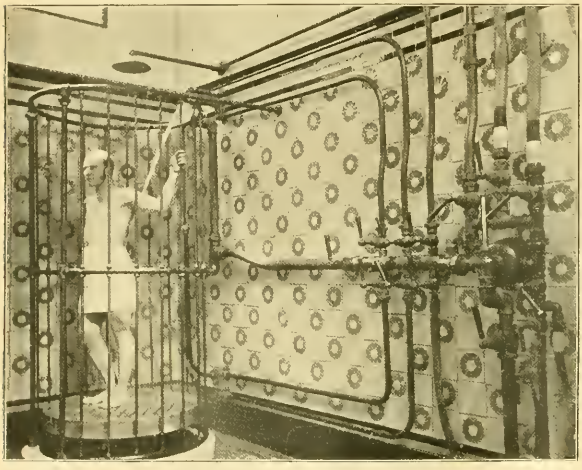
been shown to have similar effects to a less extent. Further, the group of iron waters have been examined, and their effect on the blood in the building up of hæmoglobin repeatedly proved, and other unsuspected results on the general vital processes of the body been discovered, the Chloride of Iron water, for example, markedly increasing the elimination of urea, and diminishing that of uric acid; the "Kissingen" water

increasing the flow of bile without increasing the solid constituents; and so forth. Research of this description has been and is being carried on in the health resorts of this country, and though finality has by no means been reached, yet such endeavours to add to our knowledge should go far to enhance the reputation of each, to increase the confidence of patients who seek health there, and to remove any lingering prejudices that may still remain in the minds of scientific men as to the true worth of such treatment.

With regard to the baths, inquiry as to their mode of action has proved quite as satisfactory as in the case of the mineral waters. Through the forward policy adopted at Harrogate in providing a new and magnificent suite of baths including almost every variety, and replete with every modern convenience, it is possible there to undertake and carry out any line of balneo-therapeutic treatment that may be desired. The methods in use at the continental spas have been adopted and in some cases improved upon, any new development being at once installed and its utility or otherwise determined. The baths available, using the word bath in its widest sense,



*Greaves.*] [*Harrogate.*

FIG. 4.—The combined needle and douche bath.

may be classified into (*a*) *Thermal* baths, depending for their action mainly on the element of temperature, and including plain water baths, hot and cold, Turkish, Russian, superheated air baths, &c. (*b*) *Thermo-chemical* baths, in which there is added to the effects of temperature the effect of the chemical constituents of the water. They include the saline sulphur baths, alkaline-sulphur baths, saline baths, Nauheim baths, &c. (*c*) *Thermo-mechanical* baths, in which there is added to the effect of temperature the mechanical action of the water in the form of sprays, douches, effervescence, &c., with or without the mechanical effect of massage. These include the needle bath, combined needle and douche, running sitz bath, &c., and those with massage, the Aix douche and the Vichy douche. (*d*) *Thermo-electrical* baths, in which a current of electricity, either constant or interrupted, is passing through the water.

Each and all of these baths have their special effects, and abundant observations have been made to determine them experimentally as a guide to their intelligent use. The factors at work in the human organism that are disturbed in greater or less degree by even simple baths are so many, and their interaction so complex, that it becomes a matter of great difficulty, in the first place to measure them, and, in the second place, to estimate their relative importance; while in the case of the more complicated baths, where different elements, thermal, chemical or mechanical, are brought into play to disturb these factors, some in one direction and some in another, often apparently in direct opposition to each other, the difficulty becomes even greater. Thus, while we are able to ascertain approximately the net physiological result in any given case, it is impossible in the present state of our knowledge to do more than hazard conjectures as to the exact mode by which that result was produced—to what extent one factor was concerned and to what extent another. Still, in spite of the difficulty, collation of the results of various workers at home and abroad enables us to understand in some degree the rationale of bath treatment, and to place it on a sound physiological basis.

The influence of bathing in its various forms on the animal economy is profound, and no one who has not specially observed the effects produced can form an adequate idea of how potent that influence is. Broadly speaking, it may be said that the effects produced are the result of changes that take place in the circulatory system, which is the system mainly acted upon by the factors—thermal, chemical or mechanical—that may be at work.

The heart, driving the blood with its contained nutriment, derived from the alimentary canal, through a closed system of tubing, consisting of arteries, capillaries and veins, enables that fluid to penetrate to all parts of the body, there to deliver up its charge of food to the tissues by interchange of fluid through the thin capillary wall; receiving in exchange the waste products from the tissues, and bearing them away to be eliminated from the system. Variations in the amount of blood, and the force with which it is driven into the circulation at each heart beat, and variations in the calibre of the closed system of tubing will, with other factors, determine the tension of the circulation, or fluid pressure under which the blood is working—the blood pressure, as it is called. These variations are controlled by a nerve apparatus, the vaso-motor mechanism, whereby dilatation of vessels in one region of the body is compensated for by contraction in another, and the average level of blood pressure maintained, or changes produced therein. On the integrity of this nerve mechanism, and the perfect performance of its functions, the maintenance of health largely depends, for by it the ebb and flow of vessel constriction and dilatation is controlled, and the circulation enabled to adjust itself to the rapid succession of changes that take place in the environment of the organism—changes due to gravity, posture, exercise, digestion and the like. Further, on these changes in blood pressure depends to a large extent the ebb and flow of fluid through the capillary wall, whereby nourishment is conveyed to and waste products removed from the tissues; and, consequently, where this function is impaired the nutrition of the whole body suffers. By the recent introduction of new instruments it is possible to measure directly the blood pressure in the human subject, and to observe its

variations from hour to hour or day to day; and also to measure the varying calibre of the arteries in the extremities. We are thus able to form a fairly accurate estimate of the conditions of the circulation, and from these observations to infer the completeness or otherwise of the nutritional processes on which depend the well-being of the individual. In different morbid conditions the blood pressure may deviate considerably from the normal, the vaso-motor mechanism be impaired, and the free interchange of blood plasma and tissue fluid be defective, to the detriment of the organism. Experiment has shown that the blood pressure is markedly affected by baths, some procedures having the effect of raising it and some the reverse. The effect, though at first temporary, is cumulative, so that a permanent modification of pressure may be obtained, from which it follows that an intelligent use of bathing as a therapeutic agent can so act on the circulatory system as to regulate the blood pressure, restore the normal mobility of the vessels, promote the interchange of tissue fluid, and profoundly modify nutrition. By means of these new methods we can watch closely the changes occurring under treatment, and can adjust the latter to the requirements of any particular case with a delicate nicety.

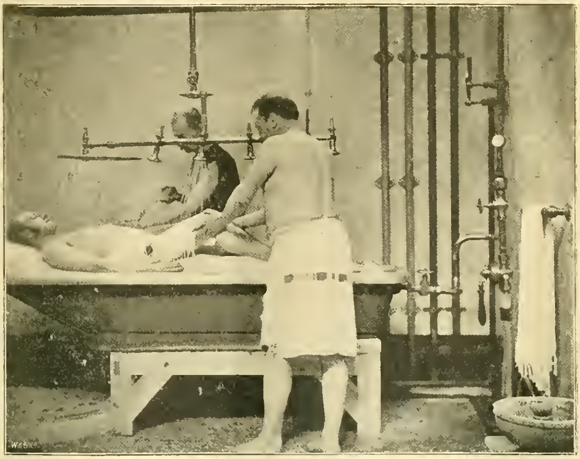
A few instances may be given of the effect of various baths on the blood pressure. Heat in all forms, whether dry as in the Turkish bath and superheated air baths, or moist as in the Russian bath, or the simple immersion bath, lowers the pressure. Cold, on the other hand, has the effect of raising it. The chemical constituents of the water in the case of the saline and sulphur baths also exert an influence, augmenting the fall in pressure resulting from warm baths. The percussion of water impinging sharply on the skin, as in the needle bath, tends to raise the blood pressure. Massage to the limbs and body causes a fall in pressure, provided the abdomen be not massaged too vigorously; deep pressure and manipulation of this part is followed by a marked rise in pressure owing to the dispersal of blood from the capacious veins of the viscera into the general circulation. In the Aix and Vichy douches massage is combined with warm douching.

In the former bath, massage is administered under a simple douche conveyed by a flexible pipe passing over the shoulder of the attendant and playing between his hands, the patient being in the sitting posture. The result on the blood pressure is to produce a fall, the massage and heat acting in the same direction. In the Vichy douche, however, the patient lies in the recumbent position, and is massaged under a needle spray falling from a bracket suspended over the table. Owing to the position adopted, massage of the abdomen is more freely performed, and this, combined with the tonic effect of the percussion of the needle spray, produces as a net result a rise in pressure.

The above considerations as to the mode by which tissue change is stimulated and nutrition modified by agents brought to bear on the circulatory system, serve to explain certain more remote effects experienced as the result of baths. To enter into these in detail is impossible within the limits of an article of this description: suffice it to mention one bath only. The Aix douche

*Graves.*] [*Harrogate.*

FIG. 5—The Aix douche.



[*Graves.*] [*Harrogate.*

FIG. 6.—The Vichy douche.

has the effect of increasing the amount of urea eliminated, and the excretion of uric acid is markedly augmented, which fact, viewed in conjunction with the diminished production of uric acid resulting from administration of the old sulphur water, explains the happy results obtained in the treatment of gout by the use of this water and bath, the one diminishing the production of the *materies morbi*, the other facilitating its elimination.

In answer to the question first propounded, it would appear then that modern research has not only abundantly justified pre-existing views as to the value of spa treatment, and has to a large extent provided sound reasons for them, but has also considerably extended its sphere of usefulness, and has uplifted the methods from the dead-level of empiricism to the more exalted domain of rational and scientific therapeutics.

The foregoing remarks suffice to show that the home watering places have of late years advanced with the times, and are able to claim equal recognition with the best known continental resorts. The variety of the waters to be found at the different health resorts of this country is such as to cover almost all requirements, and there are few cases indeed which it is really necessary to send abroad. In the matter of baths, also, almost every known balneo-therapeutic procedure is obtainable in Great Britain, and the methods of administration are as carefully supervised and as efficiently carried out as elsewhere. The one element in which we are unable to compete with our rivals abroad is in the matter of climate, for we cannot ensure the same protracted periods of sunshine that many of them enjoy. Nevertheless, the weather experienced during the season at the home resorts is not necessarily incompatible with a successful "cure," and is indeed preferred by many, by reason of its bracing qualities, to the hot and relaxing climates of some of the continental spas.

In estimating the value of spa treatment other factors besides the administration of waters and baths must be taken into consideration; such, for instance, as change of air, rest, freedom from business anxieties or household cares, regular habits of living—early rising, simple moderate diet, and so forth—all of which play their part in achieving the end in view. Therein lies the superiority of spa treatment over ordinary medicinal means in suitable cases, mainly of chronic ailments, and the impossibility of fulfilling these necessary conditions renders futile the attempt to follow out similar lines at the patient's own home. Indeed, by many the major influence is attributed to these factors rather than to baths and waters, and in some cases this may be true. But, while recognising fully their importance, the foregoing rough indication of some of the modes in which waters and baths have been proved to act suffices to show that to these the predominant influence must be assigned.

WILFRID EDGECOMBE.

## THE DOVER MEETING OF THE BRITISH ASSOCIATION.

INTENDING visitors to the Dover meeting should note that this year the chief railway companies afford additional facilities to members of the Association. They offer a return ticket at a fare and a quarter, issued from September 12 to 20, available for return till September 27. Those who wish to avail themselves of this privilege must obtain from the Secretary a signed certificate, which must be given up to the booking clerk when the ticket is purchased. The following railway companies have entered into this arrangement:—The Caledonian, Great Eastern, Great Central, Great Northern, Great Western, London, Brighton and South Coast, London and North Western, London and South Western, Midland, North British, South Eastern and Chatham and Dover. The usual arrangement for places within fifty miles of the place of meeting still holds good, in virtue of which a return ticket at a single fare may be obtained at Dover on production of membership tickets. These tickets are available for return on the same or the following day.

The local programme is now in the press. It may, however, be useful to recapitulate the items of general interest which will appear in the programme.

### SECTIONAL MEETING ROOMS.

A—Mathematical and Physical Science—School of Art, second floor.
B—Chemistry—School of Art, first floor.
C—Geology—College Gymnasium.
D—Zoology—School of Art, second floor.
E—Geography—Apollonian Hall.
F—Economic Science and Statistics—Co-operative Rooms.
G—Mechanical Science—School of Art, ground floor.
H—Anthropology—Rifle Volunteer Hall.
I—Physiology—Chemical Lecture Room, School of Art.
K—Botany—Union Hall.

### PRESIDENT'S ADDRESS AND EVENING LECTURES.

These will be delivered in the Town Hall.

*President's Address.*—On Wednesday, September 13, the first general meeting will be held at 8 p.m., when Sir Michael Foster, K.C.B., Sec.R.S., will assume the presidency and deliver an address.

*First Evening Lecture.*—On Friday, September 15, at 8.30 p.m., by Prof. Charles Richet, of Paris. Subject: "La Vibration Nerveuse."

*Second Evening Lecture.*—On Monday, September 18, at 8.30 p.m., by Prof. Fleming, F.R.S. Subject: "The Centenary of the Electric Current."

### ENTERTAINMENTS AND GARDEN PARTIES.

*Thursday, September* 14.—The Chairman of the College Council, Dr. E. F. Astley, the Headmaster and Masters of Dover College, invite members, associates, and holders of ladies' tickets to a garden party in the College Close, from 3.30 to 6 p.m.

The Mayor, Councillor Sir W. H. Crundall, J.P., and the Mayoress, Lady Crundall, invite members, associates, and holders of ladies' tickets to a conversazione at the Town Hall, from 8.30 to 11.30 p.m.

*Friday, September* 15.—Lord George Hamilton, Captain of Deal Castle, invites two hundred members, associates, and holders of ladies' tickets to visit the Castle, from 3.30 to 6 p.m.

A smoking concert in honour of the President, Sir Michael Foster, F.R.S., will be given by the Local Committee in the Apollonian Hall, Snargate Street, commencing at 10 p.m. A selection of music will be performed by the band of the Royal Artillery from Woolwich, by special permission.

*Saturday, September* 16.—A grand military tattoo will take place on the sea front, opposite Waterloo Crescent, at 9.30. A space will be reserved for members, &c. Admittance on presentation of Association ticket.

*Monday, September* 18.—The Mayor and Lady Crundall invite members, associates, and holders of ladies' tickets to an "at home" at the Connaught Park, from 4 to 6.30 p.m.

*Tuesday, September* 19.—On Tuesday afternoon, September 19, a motor-car exhibition will be opened at the Dover Athletic Grounds by the Mayor.

Lord Northbourne invites 200 members, associates and holders of ladies' tickets to visit Betteshanger Park, from 4 to 6 p.m. Light refreshments will be offered.

Lord George Hamilton, Captain of Deal Castle, invites 200 members, associates and holders of ladies' tickets to visit the Castle, from 3.30 to 6 p.m.

The Local Committee invite members, associates and holders of ladies' tickets to a garden fête in the Granville Gardens, from 9.30 to 11.30 p.m. The band of the Royal Engineers, from Chatham, will, by special permission, perform a selection of music during the evening.

### THE MUSEUM.

The Dover Museum, in the Market Square, is well worth visit, as it contains a large number of objects interesting both to

antiquarians and lovers of natural history. The collections owe much to the care and interest of Dr. E. F. Astley, the hon. curator. The assistant curator will be glad to afford visitors every assistance. The anthropological collection, though small, is interesting, and contains a valuable feathered cloak from the Sandwich Islands, a Maori's head, and many war trophies from New Zealand. The "Plomley" collection of British birds, presented by the late Dr. Plomley, is specially rich in local specimens. The collections have been enriched by many gifts from the Hon. Walter Rothschild, who takes considerable interest in the Dover Museum. There is a good collection of British birds' eggs, including those of the peregrine falcon, once common on the Dover cliffs, but now becoming exceedingly rare. Prehistoric and local antiquities are well represented. The collections of shells, insects and fossils are also noticeable.

### VISIT OF THE FRENCH ASSOCIATION TO DOVER.

On Saturday, September 16, the members of the Association Française pour l'Avancement des Sciences will visit Dover. On their arrival, about 9.30 a.m., they will partake of a light repast at the Lord Warden Hotel. At eleven o'clock there will be a reception at the Town Hall, when addresses of welcome will be delivered. Afterwards various Sectional Meetings will be visited. At 1.30 there will be luncheon in the marquee in the College Grounds. Tickets for the luncheon (price 15*s.*, including wine) will be on sale at the Reception Room. In the afternoon the members of the French Association will visit the Castle and other objects of interest in Dover.

### VISIT OF THE BRITISH ASSOCIATION TO BOULOGNE.

On Thursday, September 21, the members of the British Association will visit Boulogne. A special boat will leave Dover about 8.30 a.m., arriving at Boulogne about ten o'clock. After a reception, the various sections will be visited, and subjects mutually interesting to the two Associations will be discussed. At 12.30 the Municipality of Boulogne will entertain the Associations to lunch. The luncheon will be followed by a Reunion with addresses. In the afternoon a plaque to the English poet Campbell will be unveiled, and a statue to the French man of science, Duchenne, will be inaugurated. The afternoon will be spent in visiting the town of Boulogne. In the evening those members of the British Association who do not intend to take part in the five days' excursion will leave for Dover. Sleeping accommodation will be provided in Boulogne for those who intend to visit the towns of Northern France and Belgium on the excursion commencing the following morning (Friday).

### HANDBOOK.

The Local Committee have prepared a special handbook to Dover and the neighbourhood, containing articles on the history and antiquities, the geology, the entomology, the vertebrate fauna, the botany, the climate, the river and tides, the docks and other engineering works, the trade, commerce, and industries. This book is illustrated with maps and plans, some of which contain new work. The information given in the maps and plans and the articles, written by specialists on the subjects they deal with, will, it is hoped, render the work not only useful on the occasion of the British Association's visit, but also of some permanent value.

### EXCURSIONS.

*Wednesday, September* 20.—Excursion to Canterbury. The Mayor of Canterbury and the Corporation invite the members, associates and holders of ladies' tickets to Canterbury in the afternoon, to meet the President and one hundred members of the French Association. Special facilities will be given for visiting the various places of industry in the city. The Dean and Chapter will receive the guests at the Cathedral after the Mayor's reception at the Royal Museum.

*Thursday, September* 21.—(1) Visit of members, associates, and holders of ladies' tickets to the Association Française pour l'Avancement des Sciences at Boulogne. A special steamer will leave Dover at 8.30 a.m. (2) Excursion to Chatham Dockyard and Rochester Cathedral. Limited to 200. (3) Excursion to Wye Agricultural College, to inspect experimental farm. Luncheon will be provided by the Principal, Mr. A. D. Hall. Guests limited to eighty. (4) A circular tour through the Weald of Kent, including stoppage at about five towns between Dover and Tunbridge Wells, and extending over two days. Limited to fifty persons.

*Friday, September* 22.—There will be a five days' excursion in France and Belgium, to Abbeville, Amiens, Arras, Brussels, Antwerp, Ghent, and Ostend, at the conclusion of meeting. The excursion will start from Boulogne on Friday morning, September 22, when sleeping accommodation will be provided for those not returning to Dover after the visit to the French Association.

### CHURCH SERVICES.

There will be special services at most of the churches on Sunday, September 17. At St. Mary's there will be a special service for members of the Association at 11 a.m., when the Rev. Archdeacon Wilson, D.D. (late Headmaster of Clifton) will preach.

The railway companies will afford facilities for those wishing to visit Canterbury on Sunday. The Very Rev. Dean Farrar (Vice-President of the Association) has arranged the following special services:—

10.30 a.m.—The sermon will be preached by the Lord Archbishop of Armagh.

3 o'clock p.m.—The sermon will be preached by the Rev. Canon Mason, D.D. The sermon will be followed by an organ recital.

6.30 p.m.—The sermon will be preached by the Very Rev. the Dean.

W. H. PENDLEBURY.

## THE NEW PHILHARMONIC MUSICAL PITCH.

THE question of musical pitch has, through the action of some of the leading pianoforte makers, been again introduced into public discussion. That it should end in the general adoption of the French diapason normal hardly admits of a doubt, especially as it is in the United Kingdom only there remain any advocates for the high pitch formerly general. France introduced by law the diapason normal in 1859, and has been gradually followed by Belgium and Italy, Germany and Austria, Russia and the United States of America, leaving this country in musical isolation from which a great effort has yet to be made to bring it into uniformity with other musical countries, so that the note A will be approximately the same here as anywhere else, and not give the impression of a transposition. The difference of vibration number is not so very much; if it were a semitone, it might be easier rectified—at least in concert organs—it may be stated at 3/5, or at most 2/3 of an equal semitone. It is measurement and the important consideration of temperature that justify the admission of a subject, at the first aspect merely artistic, into the columns of NATURE. Temperature has as yet met with insufficient consideration. It is hardly alluded to in the "Sensations of Tone" by Helmholtz; it meets with a bare mention only, although somewhat extended in the footnotes of the English translator, the late Dr. A. J. Ellis, who refers (p. 90, second edition) to the experimental work in that direction of Mr. Blaikley.

It is well known that the Paris diapason normal is stated as $A=870$ vibrations a second at 15° C. As we reckon by complete vibrations, we take this number at one-half (435), with the temperature by the Fahrenheit thermometer (59°). Although this is a very good temperature for open-air music, as military bands, &c., it is not high enough for operas and concerts taking place in confined spaces with audiences and artificial lighting. The opera and concert orchestras have, therefore, everywhere to find their own pitch evolved from the Paris standard to suit an average increase of temperature. If the French Commission had decided upon 20° C. (68° F.), the necessity for an empiric proceeding would have been avoided. They might very well have adopted Scheibler's suggestion, made in 1834 at Stuttgart, of $A=440$. It is known that he worked at a temperature of about 70° F. To him we owe the only facile

tonometer, for which his pitch was really A = 439·5. It is as well to go back to the protocols of the Congress at Vienna in 1885, which led to the adoption of the French pitch in Austro-Hungary. After a unanimous acceptance of the diapason normal at 15° C. it was proposed that, in order to keep the wind instruments in performance to the initial standard vibration number A = 435, the brass and wood wind instruments, and also the organ, should be made for 24° C. (75·2 F.)!—thus introducing a second standard to be used concurrently with the first, the necessity attributable to the vibration number being increased automatically by the heating and rarefaction of the air increasing its velocity, and with the orchestral wind instruments by the breath and handling of the players. Mr. Blaikley has shown the velocity of air in pipes is always less than in free air, possibly through the friction of the walls, but in the organ flue pipes it comes so near to free air that the organ may be almost regarded as a thermometer. So high a temperature as 24° C. was not left unchallenged; a wiser determination was urged of 20°, which in practice would have proved right. However the great differences likely to arise in average temperatures due to climatic conditions, and to warming and lighting apparatus, as, for instance, gas or electricity, prevented a decision from being arrived at; so that Vienna is now, as London was pending the decision of the Philharmonic Society, using a convenient empiric pitch of about A = 440 for concert performances. Ingenious as the Viennese plan in 1885 would have been, it is wiser to have one standard with one note, A, for its expression, and one mean temperature. For brass instrument makers a B flat fork may be used, and to suit the old custom of organ-builders and pianoforte-makers, a C fork; but in preparing them equal temperament should be rigidly observed.

In 1879, at the instance of Mdme. Adelina Patti, the Covent Garden Opera adopted French pitch; a recent trial in performance satisfied me that it was at A = 440, the temperature being about 70° F., and that there had been no departure from the intention of using the French standard. Little notice has at any time been taken of this important change at the Opera; but when the Queen's Hall was opened in 1893, Mr. Newman, the manager, and Mr. H. J. Wood, the conductor, lost no time in introducing the diapason normal for all performances for which they were responsible; the proprietors going to the expense of having the organ, which had just been built at the high pitch, lowered. Mr. Henschel, in his symphony concerts at St. James's Hall, and in founding the Scottish orchestra, speedily followed. But the decisive point for this country was reached when, in July 1896, the Philharmonic Society, the most eminent musical institution in this country, elected to adopt the French diapason normal, and in the following November decided to have a standard tuning-fork for their concerts. Having consulted me, the directors accepted my suggestion for that pitch that it should be A = 439 at 68° F. Forks made for the Society by Valantine and Carr, of Sheffield, were verified by me with the aid of the Scheibler tonometer in the Science Department, South Kensington, and besides the one retained by the Society, accurate copies were presented by the directors to the Science and Art Department, the Society of Arts, the Royal Academy of Music, the Royal College of Music, the Guildhall School, Trinity College, London, and myself; the last being accessible on all lawful days at Messrs. John Broadwood and Sons, 33 Great Pulteney Street, W. The B flat is stated in the same minute of the Society as = 465, the C = 522; this last happens to be a just minor third above A = 435, an accidental, although useful, coincidence.

The vibration number 439 is really the French standard raised to an average performing temperature, theoretically by my coefficient of a thousandth part of a complete vibration a second for one degree Fahrenheit, so that for 435 the rise for the next degree is ·435. In a variety of ways I have sought an average concert temperature which I have finally taken at 68°, at which strings, wind, organ and piano should be in tune. According to my coefficient A = 435 at 59° should be A = 438·93 at 68°. The round number 439 is more convenient. Briefly expressed, my coefficient is ·5 per degree for C = 500; nearly, if not quite, the rise in free air. According to Helmholtz, the velocity of sound in dry air is at 0° C. (32° F.) 322 metres = 1089·3 feet, say 1090; according to Dr. Ellis, at 60° F. the velocity is 1200 feet per second; with this my coefficient practically agrees. In further justification, I quote the Covent Garden A = 440; the same vibration number for pianos, communicated to me by Herr Seuffert (Bösendorfer's), Vienna; the clarinet of Herr Mühlfeld, of Meiningen and Bayreuth, A = 439·5, it being understood when warm; a complete trial of all the wind instruments of Mr. Henschel's orchestra with a piano tuned to A = 439 in a room exactly at 68° F.; and lastly, the crowning triumph of the Lamoureux orchestra from Paris joining forces with the Queen's Hall orchestra in London this year, the accuracy of pitch in the performance being unassailable, A = 439! I should like to add for organs my trials of the St. James's Hall organ, at 52° C = 531 and at 72° C = 541, as one of many comparisons of this nature; and conclude with Prof. Blaserna's report of a trial at Vienna, 1885, when A = 435 at 15° C., warmed to 30° C., became A = 457·7, equivalent to raising A to a tempered B flat. If a piano were supplied for a concert intended to be French pitch, at the standard fork A = 435, in London or Paris, Berlin or Vienna, it would be too flat for performance. It would be a concession of great importance, which the musical world could not be too grateful for, if the Paris diapason normal were revised for the higher temperature, 20° C., and legalised A.D. 1900, for France at A = 439. Our Philharmonic Society has shown the way, the rest of the world would soon follow. Neither the stability of pitch of the tuning-fork nor that of a pianoforte during a concert need be considered. Dr. Ellis gives the flattening of tuning-fork as 1 in 16,000 per degree Fahrenheit; Mr. Blaikley and myself in one trial only of a concert pianoforte, ·025 per degree; but for the short time a concert lasts this must be imperceptible, the elasticity of the music wire having to be reckoned with against the least change of tension.

The objections to the A = 439 that have been urged are that wind instrument makers may take it as a starting point for a lower temperature than 68°, but not if they are conscientious? We can legislate for this no more than we can for the tendency to exceed the present high pitch, as is shown by our military bands and the majority of the brass bands in this country, in spite of Kneller Hall, which is bound to maintain the old Philharmonic pitch until the War Office releases the army from it and provides or sanctions French pitch bands. Organ-builders who can work with accurate forks and a thermometer will have no difficulty with the French pitch—indeed, nearly all are in favour of it, as are the pianoforte-makers and dealers generally, but there are some who seem to fear their instruments will suffer in brilliancy of effect by the reduction. When, however, we consider the rise in the tension of pianos during the last thirty years, due to improvement in music wire and to a great change of construction, causing in grand pianos a rise in tension equivalent to a minor third in pitch, or more; and when we reflect that the difference of pitch proposed in tuning to the new Philharmonic is only 3/5 of an equal semitone, we may see in the change more a gain than a loss by a possible increased fulness of tone-quality, and above all we shall have uniformity with the rest of the musical world.

A. J. HIPKINS.

## RIBBON AND DARK LIGHTNING.

MR. ALEX. MORTON, secretary and librarian of the Royal Society of Tasmania, has sent some photographs of lightning flashes taken by Mr. W. Aikenhead, one of which is here reproduced. The photographs were taken at night with a hand camera. Referring to them, Mr. Aikenhead remarks:—"The thunderstorm was an unusually severe one, and the atmosphere surcharged with electricity, as evidenced by the frequency and extraordinary vividness of the lightning flashes, whose brilliancy momentarily rendered objects, even at a distance, as clearly discernible as in daylight. The intensity of the 'triple' flash—of which I was so fortunate as to secure a counterfeit—was so great that for some moments I was completely dazzled. I may mention that the thunderstorm lasted fully an hour, and was at its height about 9 o'clock; and it was at this period the exposures were made with my camera."

The accompanying picture is interesting on account of the triple flash represented in it, and the dark lines apparently radiating from it. In an article printed in NATURE several years ago (vol. xlii. p. 151, 1890), Mr. Shelford Bidwell described each of these characteristics of photographs of lightning flashes, and gave explanations of them. He remarked that in nearly, if not quite, every case where broad ribbon lightning has been photographed, the camera was held in the operator's hand—a fact which naturally suggests the idea that the widened image of the flash may be due to the movement of the camera during exposure. Though it might be impossible to move the camera appreciably in the brief duration of a single lightning flash, several flashes sometimes pass in quick succession over the same path, so that they may appear side by side upon the photograph if the camera is shifted during their occurrence. Moreover, Mr. Bidwell pointed out that lightning sometimes leaves a kind of phosphorescence along its track, and this may last long enough to produce a photographic picture, even though the flash itself was instantaneous. A photograph of a triple lightning flash reproduced in NATURE of October 13, 1898 (vol. lviii. p. 570) furnishes decisive evidence that a camera can be moved quickly enough to obtain several pictures of a single luminous track of lightning. The three flashes shown in that picture are identical in shape, and it is estimated that they followed one another along the track with a frequency of about 30–35 per second.

But while it is certain that some photographs of multiple and ribbon lightning are produced by movement of the camera, others represent actual lightning of a broadened or multiple form. Commenting upon some photographs of ribbon lightning obtained by the Rev. J. Stewart-Smith, Prof. Cleveland Abbe remarked in the U.S. *Monthly Weather Review* of August 1898 that he thought that they were not taken by moving the camera during exposure. He considered that a discharge of lightning was too fleeting to be influenced by the motion of the camera. With artificial oscillatory discharges the time of the discharges and the motion of the sensitive film might be so controlled as to produce the appearance of a ribbon; but no motion of the camera seemed likely to explain the many details in the ribbon photographs of natural lightning described. Prof. Abbe thought, however, there was one flash on Mr. Stewart-Smith's plate that had every indication of being certainly an oscillatory discharge, showing lines of flow identical with those photographed by Prof. Trowbridge at Cambridge, Massachusetts, and fully maintaining his conclusion that the lightning flash is an oscillatory discharge repeated frequently to and fro within the crack in the air that is opened by the first discharge.

That lightning flashes can actually present a ribbon-like appearance, and have an appreciable duration, is borne out by a letter which was sent to the Royal Society from Buluwayo at the end of 1895, and was printed in NATURE of January 23, 1896 (vol. liii., p. 272). The writers state that they were sitting in a room when one of them called attention to a very bright lightning flash. "All of us promptly went to the door, whence we witnessed a truly extraordinary sight in the shape of three ribbons of a greenish-white lightning, which hung in the sky, motionless, for what must have been fifteen to twenty seconds. It seemed to be a long way off (in a north-westerly direction), as we heard no report of thunder whatever. There could be no mistake about it—it was as distinct as possible, and it must have lasted fifteen seconds *at least*." With evidence of this kind to consider, the reality of the ribbon appearance cannot be doubted. To obtain more definite information concerning this form of lightning and the nature of the electric discharge in an ordinary lightning flash, systematic attempts should be made to photograph lightning with cameras having a known rate of movement, and an

Photograph of lightning taken at Devonport, Tasmania, by Mr. Aikenhead.

arrangement for determining the angular diameter of the ribbon.

As to the dark ramified flashes shown upon the accompanying picture, Mr. A. W. Clayden has shown by experiment that they are due to photographic reversal. If the lens of a camera is covered up immediately a flash has been photographed, the flash comes out bright in the ordinary way in the print; if, however, the lens is allowed to remain uncovered for a minute or so, thus exposing the plate to the diffused light of the sky or the glare of other flashes, the original flash appears black upon the final print.

In the same way, the discharge of an electrical machine can be made to appear dark in a photograph by leaving the lens uncovered for about a minute after the discharge has imprinted itself upon the plate. According to this, the dark ramifications in Mr. Aikenhead's picture represent a discharge of lightning which occurred before the bright triple flash. The glare of the bright flash and the

diffused light of the sky caused the photographic reversal of the first image.

Photography thus gives no support to the view that dark lightning has a real physical existence; and Lord Kelvin's letter printed in NATURE of August 10 (p. 341), together with that by Dr. W. J. Lockyer in last week's number, show conclusively that when it is visually observed it is an effect due to fatigue of the retina.

## THE RECENT ERUPTION OF ETNA.

PROF. A. RICCO, Director of the Etna Observatory, informs us that on July 19, at 8 a.m., Mount Etna threw out from its central crater an enormous mass of vapour, stones, lapilli, and cinders, which were lifted to a height of several kilometres, and afterwards covered all the south-east slope of the volcano as far as Zofferana Etnae (altitude 600 m.), where the roads are covered by nearly a centimetre of volcanic ash. A number of stones struck the dome of the Etna Observatory (which is about a kilometre from the central orifice), so that about thirty holes were made in the iron plates, six millimetres in thickness, which cover this dome; five of these holes have a diameter of 30 centimetres, and the stones causing them fell into the observatory containing the refractor. Two stones also pierced the floor, and embedded themselves in the basement; and one broke three steps of the observing chair. Another pierced the wooden base surrounding the foot of the refractor; fortunately, this and the other apparatus of the observatory received no damage. Two other stones passed through the roofs of the side-rooms.

Round the observatory there are about fifty holes, caused by the fall and penetration of the stones in the sandy soil.

A heap of straw which was near the stables of the observatory was reduced to ashes, which proves the high temperature of the eruptive materials; moreover, holes were also burnt in the wooden flooring where it had been pierced by stones.

The steam of the eruption condensing in the air gave place to a warm and acid rain in the higher parts of the volcano, and lower down it caused ordinary rain.

The column of steam had by nine o'clock spread itself enormously in the sky nearly over Catania (a distance of 30 km.), and caused a marked darkening. By 9.30 the column had disappeared.

The eruption was accompanied by no perceptible movement of the earth, except a slight shock at the lower end of the Valle del Bove. The instruments at Catania only indicated a very slight oscillation. At the Etna Observatory two seismometers showed horizontal and vertical movements. The eruption was also accompanied by detonations, which were heard very slightly as far as Catania.

On July 25 there occurred a similar eruption, but of less importance.

## PROFESSOR BUNSEN.

ON Wednesday morning, August 16, the illustrious Heidelberg chemist breathed his last, after a long life wholly devoted to the furtherance of science. In April 1881 I communicated to the columns of this journal a sketch of the work of him whose death at the ripe age of eighty-eight all lovers of science now have to deplore. We can only now call attention to the magnitude and extent of that work, and lay on the grave of one of the truest and noblest of men the tribute of our admiration and respect. As expressing the position held by Bunsen amongst the standard-bearers of science, I may, perhaps, be forgiven for quoting the opening sentences of what I wrote eighteen years ago, as I cannot find more appropriate words to indicate what all feel who know what his work was.

"The value of a life devoted to original scientific work is measured by the new paths and new fields which such work opens out. In this respect the labours of Robert Wilhelm Bunsen stand second to those of no chemist of his time. Outwardly the existence of such a man, attached, as Bunsen has been from the first, exclusively to his science, seems to glide silently on without causes for excitement or stirring incident. His inward life, however, is on the contrary full of interests and of incidents of even a striking and exciting kind. The discovery of a fact which overthrows or remodels our ideas on a whole branch of science; the experimental proof of a general law hitherto unrecognised; the employment of a new and happy combination of known facts to effect an invention of general applicability and utility; these are the peaceful victories of the man of science which may well be thought to outweigh the high-sounding achievements of the more public professions."

In the columns which follow the above will be found a statement of the chief experimental researches which have not only raised Bunsen by the common consent of all who can understand the results of accurate and far-reaching methods to the highest point of scientific honour, but also of those more popular discoveries which have made his name a household word in circles far wider than those of purely scientific appreciation. Now, therefore, it is only necessary to recall the main facts of his life work; to note, in the first place, that his desire to unravel the secrets of nature was unalloyed by any attempt to make capital out of any application of his discoveries. "To one man," he often said, "comes the duty of discovery, to another that of applying that discovery to practical uses." Like our great countryman Faraday, Bunsen consistently refused to be drawn away from the paths of purely scientific investigation, and, though too clear-sighted a mind to belittle the importance of the application of scientific discovery to every-day life, rightly judged that to him belonged the undoubtedly higher and nobler work of enlarging the boundaries of knowledge.

The next thing to be noted about Bunsen's work is its originality and its accuracy. It matters not whether we look into his purely chemical investigations, at his chemico-geological researches, or at those—perhaps the most remarkable amongst the many questions he answered—which lie on the borderland of physics and chemistry, in every case we rise from the study not merely feeling that we have to do with a master's mind and hand, but that each investigation is stamped by an original mode of treatment and by an accuracy of thought and of manipulative power which, it is not too much to say, has rarely if ever been equalled.

In no instance was this rare combination of mental and manual dexterity more strikingly shown than in his investigation of the compounds of cæsium, the rarest of the two alkali metals which he discovered by means of spectrum analysis. In order to prepare the pure salts of this metal, some scores of tons (I write this away from books, and therefore cannot give the exact figures) of Dürkheim mineral water had to be evaporated, and from this residue it was only possible to obtain some five or six grams of the pure chloride. Nevertheless, from this comparatively minute quantity Bunsen succeeded not only in preparing and analysing all the important salts of cæsium, but in ascertaining by goniometric methods their exact crystalline form. So that he was able to supply all the information requisite to a complete understanding of the position of this new element and its compounds to those of its well-known relations potassium and sodium.

Then look at his gasometric methods. He was the first to attempt anything like exactitude in the measurement of

gases. And when he had perfected his methods, no improvements as regards accuracy were forthcoming. Other quicker and, perhaps, more handy processes have since come into vogue; but it was Bunsen who taught men how to handle and to separate and measure gaseous substances.

Next take his researches in chemical analytical methods. There we find again that all he touches he adorns. Whether in the delicate and complicated silicate analyses, in blow-pipe work and flame reactions, in volumetric methods, in separations of closely allied metals, such as antimony and arsenic, or those of the cerite earths, we see the same master's touch. Then his physico-chemical researches, his ice-calorimeter, his photo-chemical investigations, about which I am able to speak with special authority; his methods of ascertaining the specific gravity of gases by their rates of diffusion, and many other distinct lines of research, all well known and recognised as classic, exhibit the same wonderful power.

About his more popularly-known discoveries it is not necessary here to speak, save to say that the Bunsen battery and the Bunsen burner have rendered his name a household word all the world over, whilst his application of spectrum analysis to the investigation of terrestrial matter has done more than all the investigations of past time to increase our knowledge of the chemical composition of the earth's crust.

But this experimental work, great and important as it is, is not the greatest or most important work which he accomplished. It is as a teacher and as an example that the name of Bunsen is and will be chiefly honoured and remembered. It is only those who have had the benefit of working under and with him who can fully understand the feelings of affection and respect with which they regard his memory. To those who had the privilege of his intimacy, of whom I can happily lay claim to be one, his friendship will remain as an abiding source of gratification. As an investigator he was great, as a teacher he was greater, as a man and a friend he was greatest.

HENRY E. ROSCOE.

## NOTES.

THE Royal Society has received through Mr. Chamberlain the following memorandum by the Governor of the Straits Settlements:—

The Government of the Straits Settlements desires to invite the attention of Radcliffe's travelling Fellows, and of holders of scholarships for medical and physical research, to the study of the tropical disease called Beri-beri. This disease caused in the hospitals of the Colony 730 deaths in 1896 and 692 in 1897. This Government will be glad to assist any scholar who desires to engage in the scientific investigation of this disease in the Colony by providing him with furnished quarters, rent free, by giving him free access to all the hospitals and facilities for studying the cases therein, by defraying the cost of his passage to the Colony, and in any way which may be agreed upon hereafter between the scholar and the undersigned.

By Command of the Governor,

J. A. SWETTENHAM,
Colonial Secretary, S.S.

Colonial Secretary's Office,
Singapore, July 20.

It may be added that Dr. Hamilton Wright, late of Montreal, has recently been appointed pathologist to the Straits Settlements. He will be provided with an adequate laboratory, on the furnishing of which he is now engaged. The opportunities for pathological research will therefore be extremely good.

THE eighteenth annual Congress of the Sanitary Institute was opened at Southampton on Tuesday, when about seventeen hundred delegates attended. Sir William Preece, K.C.B., the president, delivered his inaugural address, in which he dealt with the principles underlying practical applications of sanitary engineering.

MR. A. H. MILNE, hon. secretary of the Liverpool School of Tropical Diseases, informs us that in response to a request from Major Ross that workers should be sent out to join him at Sierra Leone, the school is despatching, as an assistant to him, Dr. R. Fielding Ould, of the Liverpool School of Pathology, who has had special experience in private bacteriological research. It is to be hoped that the Government will take the matter in hand, and will help the work of the expedition.

WE learn from *Science* that Dr. A. B. Meyer, Director of the Dresden Museums, is now in the United States on a commission from the Saxon Government to inspect American museums before the new buildings are erected at Dresden. He is accompanied by Prof. P. Wallot, who is one of the international commission of architects selected to decide on the plans of the University of California in accordance with Mrs. Hearst's arrangements.

A *Reuter* telegram from Potsdam states that the new observatory and the great refractor, recently erected at the Astrophysical Observatory there, were inaugurated on Saturday, August 26, in the presence of the German Emperor.

OUR photographic readers may be reminded that all entries for the Royal Photographic Society's forty-fourth annual exhibition, to be held at the Gallery of the Royal Society of Painters in Water Colours from September 25 to November 11, close on Wednesday, September 6, at 9 p.m.

THE Allahabad *Pioneer Mail* states that an Austrian scientific party will visit India towards the latter end of October to observe the display of Leonid meteors which will take place in November. Two observation stations are to be fixed at Delhi, some five miles apart, telephonic communication being maintained under arrangements made by the Telegraph Department.

DR. A. CANCANI, formerly assistant at the geodynamic observatory at Rocca di Papa, has been selected to succeed Dr. G. Agamennone as assistant in the central office of meteorology and geodynamics at Rome. Dr. Cancani is well known to seismologists for his work in connection with the velocity of earthquake-waves, and for the improvements which he has made in the pendulums designed for recording the undulations from distant earthquakes.

REFERENCE has already been made to the fact that the section of the tree under which Dr. Livingstone's heart was buried, containing the inscription carved by his followers, has been obtained for preservation in the Royal Geographical Society's collection of relics. The *British Central Africa Gazette*, published at Zomba, gives the following particulars of the journey to obtain the section:—Mr. Codrington, Deputy Administrator for the British South Africa Chartered Company north of the Zambesi, left Fort Jameson (Mpezeni's) on April 24, and reached Chitambo on May 9. From the present village of Chitambo he travelled with Chitambo ten miles E.S.E., three miles to the Msumba river or swamp, and then seven miles to the Luwe river. These streams flow into the Lulimula river, and that into the Luapula. Chitambo states that his father was interred under the *Mpundu* tree close to the spot where Livingstone's heart was buried. The following measurements were taken of the tree: Round base, 13 feet 5 inches; round bottom of inscription, 10 feet 1 inch; round top of inscription, 10 feet; height of bottom of inscription from ground, 4 feet 5 inches. The bark was cut off by Livingstone's men in order

to enable the inscription to be carved, and it has now grown over part of the letter "E" in Livingstone and over the number "3" in 1873. Livingstone's *Mpundu* tree was too old to give seeds, so it was not possible for Mr. Codrington to bring away any of these. After the tree had been cut down, and the section containing the inscription carefully removed, a tall iron telegraph pole was erected in the entre of the stump and carefully secured. This, together with the various observations taken, will suffice to mark the exact spot until a suitable monument may be erected. The altitude (by boiling point) at the *Mpundu* tree was found to be 3877 feet above sea level.

MR. W. WELLMAN and the American members of his polar expedition arrived at Hull on Tuesday from Tromsö. In addition to the information published in last week's NATURE (p. 399) concerning the results of the expedition, the following particulars were given by Mr. Wellman to a representative of Reuter's Agency:—"The point at which we turned back was about twenty-five miles north-west of the Freeden Islands, where Dr. Nansen landed in 1895, and north of these islands we saw and took the bearings and photographs of three islands and a large land, none of which had been seen by either Payer or Nansen. We were also able wholly to clear up the mystery of Payer's so called Dove glacier, which simply does not exist, as Dr. Nansen had in part shown. In addition to this useful geographical work, greatly augmented by subsequent journeys under Messrs. Baldwin and Harlan, these two gentlemen and Dr. Hoffmann, the naturalist, did some valuable scientific work which will, I feel sure, attract much attention when elaborated and reported in proper form. I still believe it possible to reach the North Pole by Franz Josef Land, but whether or not I shall make another effort in that field I am unable to say." After Mr. Wellman's return to headquarters on April 9 Mr. Baldwin again took the field, leaving camp on April 26, accompanied by the four Norwegians, this party having twenty-six dogs and two sledges, carrying provisions for three weeks. Their object was to examine the unknown region to the eastward of Wilczek Land. They were enabled to chart the entire eastern as well as north coasts of that land. Thirteen miles further east they discovered a large ice-covered island nearly as large as Wilczek Land and extending to 64° E. longitude. Several smaller islands were also discovered during this journey. The newly-discovered land was named Graham Bell Land, after the president of the National Geographical Society of America. Another exploring journey was made by Mr. Harlan, and later a trip by steamer, the result being a fairly complete survey of the unknown and unmapped parts of the archipelago.

THE practical application of the Röntgen rays to the needs of medicine and surgery formed the subject of the presidential address recently delivered before the Röntgen Society by Dr. C. M. Moullin. There is no branch of medicine or surgery which does not afford abundant evidence of the improvements which have taken place in the production and utilisation of the Röntgen rays in the course of the past year. Dr. Moullin points out that the fluorescent screen has now reached such a degree of perfection that with suitable apparatus the minutest movement of the heart and lungs, and the least change in the action of the diaphragm, can be watched and studied at leisure in the living subject. In short, Dr. Moullin testifies that there is scarcely any change in connection with the lungs and the heart and great vessels which cannot now be seen and photographed, scarcely a disease of the chest or of the organs which it contains concerning which the most valuable information cannot be obtained. To such an extent has the fluorescent screen been improved, and so easy has investigation with it been made, that it is probable that some day the examination of a patient's chest with it will be considered as much a matter of routine and as little to be neglected in all doubtful cases as an examination with the stethoscope is at the present time. Valuable as are the indications given by the ophthalmoscope in obscure diseases of the brain, they are not to be compared with those which can be obtained by systematic and skilled use of the fluorescent screen in diseases of the heart and lungs.

THE benefit which surgery has derived from the improvements which have been effected in the use of the Röntgen rays during the past year is, Dr. Moullin states, no less striking than that gained by medicine. As might be expected, the largest proportion and the most striking cases have been furnished by the injuries and diseases of bones and joints. With a well-lit fluorescent screen the nature of an injury can be seen at once, and, what is even more valuable, it is no less easy to ascertain whether a fracture is properly set or a dislocation completely reduced. If the screen is of service to physicians in the diagnosis of intra-thoracic disease, the records of the past year have shown by numberless instances that it is no less valuable to surgeons by enabling them to make sure at a glance that the bones are in their proper relative situation without touching the splints or giving the patient a moment's pain. So far as surgery is concerned, Dr. Moullin remarks, nothing illustrates the immense improvement which has been made in radiography in the course of the past year better than the detection of renal calculi. Until this year the instances in which they had been photographed and verified by operation were few and far between. Now, thanks more particularly to the work of Mr. Mackenzie Davidson in this direction, the detection of renal calculi can be looked forward to with a fair degree of certainty, and, what is even more valuable, as saving patients from unnecessary operation, the evidence can be trusted equally well when it is negative. In all ordinary cases it may be said that if no calculus is seen there is no calculus there to see.

FROM reports in the *Agricultural Journal*, published by the Cape Department of Agriculture, it appears that much success in exterminating locusts by inoculation with the locust disease fungus has been attained in many districts. The fungus is prepared and supplied by the Director of the Bacteriological Institute, Graham's Town, at a cost of sixpence per tube to all applicants residing in Cape Colony. One of the reports upon its use states that over a hundred locusts which were inoculated with fungus disease were distributed amongst a swarm, and on the next morning and the following days large numbers of dead ones were in the sand dunes, being killed by the fungus, as microscopical examination and further experiments with the bodies proved. The growth of fungus from the dead locusts produced a fungus more rapid in growth but smaller in size than the Government fungus. In another case, the fungus was mixed in lukewarm water, and young locusts were released after immersion in the liquid. After three days rain fell, and on the afternoon of the fourth day locusts were found in heaps in the bushes about three miles from where they were immersed. Districts in which no such measures are being taken are much more infested with locusts than those where the fungus treatment is adopted.

SEVERAL articles and notes upon india-rubber and the india-rubber industry in various parts of the world are contained in Nos. 147-150 of the *Bulletin* of the Royal Gardens, Kew, just published. A paper by Prof. Tilden on the spontaneous conversion of isoprene into caoutchouc is reprinted, and it is pointed out that the result represents a step towards the artificial production of india-rubber commercially. Prof. Tilden has not yet been able to bring about this change at will. His observations show that the polymerisation proceeds very slowly, occupying several years, and all attempts to hurry it have resulted in the

production, not of rubber, but of colophene—a thick sticky oil, quite useless for all the purposes to which rubber is applied. The *Bulletin* publishes correspondence showing how the falling off in the production of rubber at Lagos is due to the reckless way in which the trees have been exhausted. The rubber is collected from the Ire tree (*Kickxia africana*), and has been an important source of wealth to the Colony; but the industry is rapidly decreasing, owing to want of control over the collectors who tap young trees, and destroy rubber forests by over-working. In Madagascar efforts are now being made to establish plantations of rubber-producing plants. The island has long been known to furnish a supply of india-rubber to commerce, the rubber being obtained until a few years ago from species of Landolphia—the rubber-vines, which are so widely distributed in tropical Africa About 1892 another source of rubber was exploited, but unfortunately both the trees and shrubs producing rubber have been ruthlessly destroyed, and it is necessary to take active steps to cultivate rubber plants to preserve the industry. The May and June *Bulletin* contains correspondence which indicates the actual source of Peruvian india-rubber. According to the information received, the Caucho tree of Peru is a Castilloa.

*Bulletin*, No. 56 (April 1899), of the West Virginia Agricultural Experiment Station, Morgantown, consists of a report on investigations to determine the cause of unhealthy conditions of the spruce and pine from 1880–1893. This is one of the admirable series of reports which are now issued regularly in many parts of the United States, in order to cope with the immense destruction wrought by insects in that country, resulting, during the fourteen years mentioned above, "in the death and total loss of many hundred thousand dollars' worth of the finest timber in the State" of Virginia. Entomology is no child's play in the States, and Prof. Hopkins enumerates 197 species of insects, observed by himself as infesting the spruce and pine, about half of which are injurious, the remainder being beneficial as parasites of the destroyers, or indifferent. These belong to all orders of insects except Orthoptera, and we imagine that a careful search would be able to fill up this gap by the discovery of some Blattidæ, at least, under loose bark, or in similar situations. Most of the mischief, however, is done by wood-boring beetles, of which, and of their curious burrows, many illustrations are given. There is also an illustration of a portion of a black spruce tree eight inches in diameter, which had been slightly injured, when a colony of large black ants (*Camponotus pennsylvanicus*) took possession, and hollowed out the trunk till the heart-wood was completely destroyed, and the tree fell. This report should be of great interest both to entomologists and foresters, for our own conifers are liable to the attacks of a large number of insects congeneric with many of those here mentioned, though others (as for instance *Camponotus*, just referred to) do not inhabit this country.

IN the U.S. *Monthly Weather Review* for May, there is a useful summary of the climatology of the Isthmus of Panama, by Brigadier-General H. J. Abbot. The first Panama Canal Company made daily observations at Colon, Gamboa and Naos during the years 1882–7, from which it is seen that the temperature differs very slightly during the year. At Colon the mean of the absolute maximum temperature varies from 89°·6 in February to 91°·9 in October; and the absolute minima from 68°·4 in January and April to 70°·5 in October. At Gamboa the absolute mean maximum was 97°·5 in June, and the minimum 59°·4 in February; and at Naos these means were respectively 96°·3 in June and 66°·7 in March. Throughout the whole Isthmus the rainy season begins with May; owing to the northward advance of the layer of rising air, a diminution takes place in July, in the interior, but is subject to the delay of one month on the Pacific side and of two months on the Atlantic side. A second maximum occurs at the end of September in the interior, but at the end of October on the Pacific coast and in the middle of November on the Atlantic coast. Then comes the dry season, which begins everywhere about January 1, and continues for four months. The mean annual rainfall is 120 inches on the Atlantic coast, 93 inches in the interior, and 62 inches on the Pacific coast. Although the rainfall is large, it is comparable with the amounts registered in the United States near the Gulf of Mexico. The paper contains a number of fragmentary observations referring to other periods, for which hourly or monthly variations from mean values have been calculated.

WE have received from the Observatory of Manila, of which the director is Father J. Algué, S.J., a volume (pp. xvi + 192, 4to) entitled "Las nubes en el Archipiélago Filipino." The observatory was one of the institutions invited by the International Meteorological Committee to take part in the special observation of clouds during a year ending May 1897. The volume in question, owing to delay in preparation of the necessary instruments, contains results from June 1, 1896, to July 31, 1897. The work is divided into two parts, giving (1) an account of the principal nephoscopes and theodolites in use, and the results obtained in the Philippine Islands by means of some of them; and (2) an explanation of the methods used in the photogrammetric measurements of the heights and velocities of the clouds, and the valuable results obtained at the Manila Observatory. The volume also contains an interesting account of the importance of the observation of the movements of upper clouds for the purpose of storm prediction.

THE "Eight Queens Problem" is the problem of finding the different ways in which eight queens might be arranged on a chess-board so that no two should be in check of each other; in other words, the number of ways of arranging eight pieces so that no two shall be in the same row, column, or line parallel to a diagonal. This problem, which has occupied the attention of Nauck, Gauss, Günther, Glaisher, Rouse Ball, and Pein, forms the subject of a paper by Dr. T. B. Sprague in the *Proceedings* of the Edinburgh Mathematical Society. There are ninety-two solutions, but these are not all independent, for in general each solution gives rise to four altogether by simply rotating the board, and this number is doubled by taking the reflections of these in a mirror, the exception to this rule being when the pieces are symmetrical about the centre. Mr. Sprague considers the general problem for a board of $n^2$ squares. This problem was reduced to one in determinants by Günther and Glaisher, thus: if a determinant is constructed in which terms in lines parallel to one diagonal are represented by the same letter, and those in lines parallel to the other have the same suffix, the solutions are the terms of the determinant in which no letter or suffix occurs twice. The solutions for squares with one to ten squares in a side were given by Pein, and the ten-sided square possesses 724 solutions. Mr. Sprague has now given the solutions for an eleven-sided square, which are 2680 in number, but he considers it would be necessary to obtain the co-operation of a number of persons in order to classify the solutions for larger squares.

VERY little has hitherto been recorded in regard to the life-history of those peculiar North American rodents locally known as Sewellels, and scientifically as *Haplodon*. It is therefore satisfactory to have a description of the habits and environment of one of the species, from the pen of such an accurate observer as Dr. D. G. Elliot, in the March issue of the *Publications* of the Field Columbian Museum. The Sewellels, which constitute a somewhat isolated family by themselves, are animals of the size of a small rabbit, but with a more beaver-like appearance

and coloration, although short-tailed. The species inhabiting the Olympic Mountains is known to the natives as the "Mountain Beaver," or "Farmer," the latter being the title most commonly employed. Retiring in its habits, it keeps to wet and swampy places in the neighbourhood of small streams, making its burrows in the banks of the latter. Although when in the bushes its movements appear to be exceedingly quick, yet when in the open it is rather slow. These animals obtain their name of "Farmer" from their habit of making "hay." They usually excavate their burrows in the vicinity of a certain water-plant, apparently a kind of low-growing water-lily. The stems and leaves of this plant the little rodents cut down in large quantities and convey to the mouths of their burrows, where, after being spread out to dry in the sun, they are finally carried into the interior to be used as food and bedding.

IF the history of "type specimens," on which museum curators now set so much store, were written, portions of it would read almost like a romance. A case in point is afforded by Dr. Jentink's account of the rediscovery of the type of the peculiar Malagasy carnivore *Fossa daubentoni*, published in *Notes of the Leyden Museum* for October last. In 1872, Gray, after searching the Paris Museum, came to the conclusion that the type described by Schreber was irretrievably lost. Subsequently, however, an imperfect skull turned up in the Paris Laboratory of Comparative Anatomy, which it was thought might belong to the missing specimen. And now Dr. Jentink has discovered in the Leyden Museum a skin with a cast of the Paris skull placed in it, which is undoubtedly the long-lost specimen. It is stated to have been received from Paris in 1835, and appears to be one of the results of an exchange effected by Temminck and Schlegel, who visited the Paris Museum in that year. Incidentally Dr. Jentink shows that "Fossa" is the proper native name of the animal in question, and that it is not applicable to the *Cryptoprocta ferox*, of which the Malagasy title is "Farassa." This alteration should accordingly be made in our text-books.

IN the July and August numbers of the *Zoologist*, the editor, Mr. W. L. Distant, gives the first two instalments of what promises to be a very interesting discussion on "mimicry." Till the communication has reached a more advanced stage, it will obviously be impossible to learn the author's general views on a very difficult and very important subject; but it may be noted that he intends to divide the alleged cases of mimicry into those considered as "demonstrated" and those classed as "suggested or probable," after which we may expect a fuller discussion on the whole subject. In the first section of his communication Mr. Distant takes up the case of the Stick-Insects (*Phasmidae*), and discusses their bearing on the mimicry theory. These insects, he states, are usually considered as undoubted examples of protective resemblance due to natural selection. If, as has been asserted, they are represented in the Carboniferous, they must be the result of an antecedent evolutionary process. Further, the presence of imitative *Phasmidae* in the Carboniferous implies the existence of enemies, probably reptiles, and possibly transitional forms of bird-life. Thus mimicry must be of very ancient origin; whence it is argued that some cases of it in existence without any apparent reason may be due to survival, and are now altogether useless to the animals in which they occur. The alleged protective resemblance of fishes to their surroundings is, the author suggests, not the true explanation of their colouring, their extraordinary fecundity being, in his opinion, sufficient to override the necessity for any such protection. We shall await with interest further instalments of this communication.

IN the August number of the *Zoologist* a discussion is being raised as to the manner in which the helpless and shapeless new-born young of the kangaroo is transferred to the materna pouch and affixed to the nipple from which it is to derive nutriment. Some have said that it is carried in the paws of its female parent, while one asserts that the transference takes place by the aid of the lips, and that it has been actually witnessed in the Zoological Gardens. This, however, we gather from Mr. E. Bartlett's communication, is not the case. It ought to be possible to decide the point by actual observation in a menagerie.

THAT the Edinburgh Geological Society, under the presidency of Mr. John Horne, is in a flourishing condition is manifest from the record of its *Transactions*, of which we have lately received Part 4 of vol. vii. for 1899. Mr. J. G. Goodchild contributes a short and appreciative memoir of the late Prof. Heddle, with a portrait of that distinguished mineralogist. This article is followed by a short paper, which was read before the Society in 1856, by Heddle, and not previously printed; it deals with the minerals of the Storr, near Portree. There is a useful paper on the subdivisions of the Carboniferous series in Britain and their European equivalents, by Dr. Wheelton Hind, who shows to what extent at present he has been able to subdivide our rocks into palæontological zones. Mr. William Gunn discourses on the Lower Carboniferous rocks of England and Scotland. Mr. Herbert Kynaston contributes notes on the petrology of the Cheviot Hills; and there are various other papers of local interest. A short article by Mr. E. Greenly on the Hereford earthquake of 1896 might more appropriately have been printed in the *Transactions* of a Welsh or West of England Society, as it deals with the relations of this disturbance to geological structure in the Bangor-Anglesey region.

A REPORT on the surface geology and auriferous deposits of South-eastern Quebec has been prepared by Mr. R. Chalmers (Geol. Survey of Canada, Part J, *Ann. Rep.*, vol. x.). The author has devoted particular attention to the glacial and other superficial deposits in the St. Lawrence valley, as it is chiefly in these that gold is found in workable quantities. The primary source of the gold is traced to the crystalline schists of Pre-Cambrian or Huronian ages; schists which were invaded by diorites and other intrusive rocks, and which afterwards yielded materials to the basal Cambrian conglomerates and later deposits. In these Cambrian and Silurian rocks much gold would have been disseminated in a fine state of division. After the consolidation of these rocks, upheaval, crumpling, faulting and metamorphism would seem to have taken place; and Mr. Chalmers thinks that the gold was probably brought up in solutions and concentrated along with silica and the metallic sulphides in faults and fissures, thus forming auriferous veins. Much gold was long afterwards distributed in superficial deposits during pre-Glacial times in ancient river-beds; and these deposits and the material of old weathered surfaces of the crystalline rocks have been partially removed and redeposited time after time during the changes of Glacial and post-Glacial times.

WE have received the general report on the work carried on by the Geological Survey of India during the year ending March 31, 1899, under the direction of Mr. C. L. Griesbach. Field-work has been carried on in the Raipur district, in South Rewa, and in Western Rajputana; and after many years' intermission the geological survey of the higher ranges of the Himalayas has been resumed. Trilobites of the family *Olenidae* have been found in the Upper Haimantas slates, showing that they are probably of Upper Cambrian age. The occurrence of Ammonites (*Xenodiscus* and *Arcestes?*) is noted in the *Productus*-shales of Carboniferous age. Field-work has also been carried on in Baluchistan, where Jurassic, Cretaceous, and Tertiary strata have been mapped. In the Cretaceous system,

zones of *Gryphaea vesicularis*, *Radiolites*, *Ostrea acutirostris*, &c., are noted. Economic geology rightly received considerable attention, and the mineral Mica was selected for special study. Records are also given of the important work done in the Laboratory and in the Palæontological Department.

THE fourth edition of "Remarkable Eclipses," by Mr. W. T. Lynn, has just been published by Mr. Edward Stanford. Reference is made to the results of observations of the Indian eclipse last year, and to the eclipse which will occur on May 28, 1900. The central line of this eclipse will pass from America across Portugal, Spain and Algeria.

THE tenth annual report of the Missouri Botanical Garden has recently been published. Dr. W. Trelease, the Director of the Garden, states that the collection of plants now includes more than eight thousand species and varieties, of which all but one or two hundred are named with more or less accuracy. Among the collections specially worthy of mention are the cacti, of which 462 species are cultivated; the orchids, represented by 548 named forms; the aroids, of which there are 274 species in the collection; the ferns, including 169 species; and palms, 61 species; while of hardy trees and shrubs there are 1811 species and varieties; of hardy herbaceous plants, 2179; and of vegetables, 1016. Roughly divided, the collection includes 5000 hardy forms, and 3000 cultivated under glass. The Herbarium comprises 307,460 specimens. Two scientific papers are included in the present report: one on the grasses in the Bernhardi Herbarium in the Missouri Botanical Garden, and another on a sclerotioid disease of beech roots. There is also a biographical sketch, by Prof. C. S. Plumb, referring to the late Dr. E. Lewis Sturtevant, whose gift of his extensive and valuable library of pre-Linnean works was an event in the history of the Garden; and a list of publications issued from the Garden in 1897 and 1898.

THE additions to the Zoological Society's Gardens during the past week include a Serval (*Felis serval*) from Africa, presented by Sir R. B. Llewellyn, K.C.M.G.; a Macaque Monkey (*Macacus cynomolgus*) from India, presented by Mr. T. Mark Merriman; a Bonnet Monkey (*Macacus sinicus*) from India, presented by Mr. J. M. Skinner; a Spotted Ichneumon (*Herpestes auro-punctatus*) from Nepal, presented by Miss Jackson; a Red-faced Onakari (*Onacaria rubicunda*) from the Upper Amazons, a Red-vented Cockatoo (*Cacatua hoematuropygia*) from the Philippine Islands, deposited; two Lion Marmosets (*Midas rosalia*) from South-east Brazil, four Violet Tanagers (*Euphonia violacea*), three Blue-shouldered Tanagers (*Tanagra cyanoptera*), a Black-headed Sugar Bird (*Chlorophanes viridis*) from Brazil, a Black-necked Swan (*Cygnus nigricollis*) from Antarctic America, purchased.

## OUR ASTRONOMICAL COLUMN.

ASTRONOMICAL OCCURRENCES IN SEPTEMBER:—

| | | |
|---|---|---|
| September 4. | 19h. | Mercury at greatest elongation (18° 2′ W.). |
| 9. | 7h. | Jupiter in conjunction with moon (♃ 4° 51′ N.). |
| 12. | 6h. | Saturn in conjunction with moon (♄ 1° 55′ N.). |
| 12. | 8h. 47m. to 9h. 26m. | Occultation of 39 Ophiuchi (mag. 6·0) by the moon. |
| 13. | 5h. 5m. to 6h. 9m. | Occultation of 1 Sagittarii (mag. 5·3) by the moon. |
| 14. | 11h. 47m. | Minimum of Algol (β Persei). |
| 15. | Mars. | Illuminated portion of disc 0·967. |
| 17. | 8h. 36m. | Minimum of Algol (β Persei). |
| 19. | 6h. 25m. | Transit (ingress) of Jupiter's Sat. III. |
| 23. | 15h. 29m. to 16h. 25m. | Occultation of $A^1$ Tauri (mag. 4·5) by the moon. |

HOLMES' COMET 1899 *d* (1892 III.).—

SPECTRA OF RED STARS (SECCHI'S TYPE IV.).—In the *Astrophysical Journal*, vol. x. pp. 87–112, Messrs. G. E. Hale and F. Ellerman contribute the first of a proposed series of papers describing the additional work they have done on these stars since the first investigations in January 1898. The photographs have been obtained with the Yerkes 40-inch lens, which being corrected only for the visual rays, somewhat limited the region of spectrum available, until a correcting lens was obtained. This consists of a compound lens of 32 mm. aperture, supported in the cone of rays from the 40-inch objective at a distance of about 30 cm. from the slit of the spectroscope. The introduction of this lens decreases the focal length of the objective for light of λ 4500 by about 60 mm., but at the same time it so alters the original steepness of the colour-curve that it is found possible to photograph a much larger extent of spectrum at the same time.

The spectroscope originally used has been considerably modified. The collimator lens has an aperture of 31 mm. and focus of 507 mm. Three prisms of dense flint ($\mu$ = 1·696) are available, and for most of the work it has been found best to use a short camera, aperture of lens (a photographic doublet) being 37 mm. and its focal length 271 mm.

The width of the photographed spectra is usually about 0·18 mm.; the scale of the negatives is such that

at λ 4400, 1 mm. = 18·5 tenth metres;
,, λ 5350, 1 mm. = 49·6 tenth metres.

The authors proceed to describe in minute detail their methods of measurement and reduction, introducing a very ingenious *interpolating* machine they have devised to draw the reduction curves as accurately as possible.

Several illustrations accompany the article, showing the breech-piece of the 40-inch with various spectroscopes in position, two views of the interpolating machine, and a reproduction of the spectrum of 152 Schjellerup extending from λ 4800 to λ 6300. With respect to the latter, attention is drawn to the apparent bright line at λ 5592. The authors find it is easily photographed with *four minutes*' exposure, while to obtain the continuous spectrum adjoining of equal density takes from 12 to 15 minutes. This they think is in favour of its being a true bright line. From its appearance, they think it probable that whatever substance produces this line must exist in the star's atmosphere at a level *above* that of the carbon or hydrocarbon vapour which produces the heavy absorption-bands.

PHOTOMETRY OF THE PLEIADES.—Herren G. Müller and P. Kempf, of the Potsdam Observatory, have been investigating the brightness of the component stars of the Pleiades group, and the greater part of *Astr. Nach.* (Bd. 150, Nos. 3587–8) is devoted to their communication. They begin by giving tables showing the values obtained for the magnitudes of the principal stars by previous authorities, including Lindeman, Pickering, and Pritchard, and also an analysis of these values showing the varying discrepancies between the several measures of the same star. Then follows an account of their work of determining the magnitudes of 96 stars of the group, the instrument used being a Zöllner photometer in conjunction with telescopes of varying apertures. Full details are given of the preliminary experiments made for determining the constants of the instruments, &c., using certain of the stars as standards.

THE SYSTEM OF SIRIUS.—In the *Astr. Nach.* (Bd 150, No. 3588), Herr H. J. Zwiers, of Leiden, gives a revision of his previously calculated elements for the Sirius system (*Astr. Nach.*, No. 3336), which he has been enabled to make by employing the recent measures of Messrs. Aitken and Hussey,

made at Mount Hamilton during 1898 and 1899. The elements he gives are the following:—

*System II.*

| | |
|---|---|
| $T = 1894 \cdot 0900$ | $i = 46^\circ\ 1' \cdot 9$ |
| $\mu = -7^\circ \cdot 37069$ | $\Omega = 44^\circ\ 30' \cdot 2$ (1900) |
| $P = 48 \cdot 8421$ years | $\pi - \Omega = 212^\circ\ 6' \cdot 4$ |
| $e = 0 \cdot 5875$ | |

The mean value of the distance of the companion is given as

$$a = 7'' \cdot 594.$$

CATALOGUE OF ASTRONOMICAL INSTRUMENTS.—Sir Howard Grubb has sent us a revised edition of his catalogue of astronomical instruments, observatories, &c., showing the nature of the work turned out from his workshops at Rathmines, Dublin. The quality and performance of these are well known to practical astronomers, the catalogue in its new form will be interesting to all from the beautiful illustrations with which it is furnished, showing in a most convincing manner the capabilities of various optical and mechanical contrivances. The frontispiece is a reproduction of a photograph of $\eta$ Argus taken with the astrographic telescope at the Cape Observatory. At the end of the volume there are four plates showing "The solar eclipse of 1898," "A specimen of work done by a photographic doublet of 15 inches aperture," "The great nebula in Orion," and "The Dumb-bell nebula in Vulpecula"; the two latter being from negatives taken by Mr. W. E. Wilson with a reflector of 24 inches aperture.

## THE CAPE OBSERVATORY.

THE annual report of Her Majesty's Astronomer at the Royal Observatory, Cape of Good Hope, for the year 1898, has recently been published. The following is a short *résumé* of the chief details:—

*The McClean Telescope.*—The equatorial mounting of this instrument, the generous gift of Mr. F. McClean, F.R.S., reached Table Bay in good order on April 11, 1898. In six weeks all the parts had been mounted and adjusted, the stand, however, requiring considerable modification. The fittings for electrical illumination of the circles, scales, and micrometers had to be made or remodelled at the Cape.

The hydraulic motor for rotating the dome arrived on July 4, the hydraulic ram and valves for automatic clock-winding on October 11, and by November 1 all the essentials of the observatory and stand were fitted and in good working order. The raising and lowering of the floor and rotation of the dome are commanded by cords which may be actuated by the observer at the eye-end of the telescope with the utmost ease and delicacy, while the hydraulic clock-winding gear, contrived by Mr. McClean, automatically winds up the clock-weight at short intervals without communicating the slightest vibration to the telescope.

The 18-inch visual object-glass has proved to be a very fine one, both its spherical and chromatic corrections being practically perfect, as far as the kinds of flint and crown glass at present procurable in discs of that size will allow.

The 24-inch glass has two faults: the marginal images show well-marked *coma*, and the minimum focus, instead of being near to or more refrangible than $H\gamma$, is for rays of refrangibility between $H\beta$ and $H\gamma$. It is understood that Sir Howard Grubb will remedy these defects. The slit spectroscope for line of sight work, made by the Cambridge Scientific Instrument Company, was shipped from London on December 21, and the 24-inch glass cannot be returned for alteration until tests have been made with this spectroscope in conjunction with it.

*The New Transit Circle.*—The foundations for the new transit circle have been built, and the observatory, of sheet steel, is constantly expected from Messrs. T. Cooke and Sons, of York. Messrs. Troughton and Simms reported that the transit circle itself would probably be ready in March 1899.

*Astronomical Observations.*—The work of the *transit circle* has been chiefly devoted to observations of standard stars for reduction of the measures of the "Catalogue Photographic Plates." During the year 10,355 meridian transits and 9863 determinations of zenith distance have been recorded.

With the *Heliometer* systematic observations of the major exterior planets have been made, the year's work including fifty-three measures of Jupiter, forty-four of Saturn, forty-five of Uranus, and seventy-two of Neptune, all during opposition. This instrument has also been employed in the triangulation of twenty-one stars surrounding the South Pole, and for investigation the possibility, first suggested by Dr. Rambaut, of atmospheric chromatic dispersion affecting the accuracy of heliometer observations. The *seven-inch equatorial* has been employed for observations of occultations, revision of star-lists, and Coddington's comet; and the *six-inch telescope*, in conjunction with a Zöllner photometer, for the comparison of photographic and visual magnitudes in areas near the pole and equator of the Milky Way.

With the astrographic telescope, 469 plates have been obtained, 200 of these being "revision plates," as it is proposed to repeat the whole series of catalogue plates, in order to bring the epoch at which the plates were taken nearer to that at which the comparison stars were observed on the meridian.

*Geodetic Survey of South Africa.*—The field operations in connection with the geodetic survey of Rhodesia were resumed in May at the close of the rainy season, the early part of the year having been spent in training the observers in the use of the Jäderin base-measuring apparatus, the constants of which were accurately compared with the Cape measuring bars. The difference of longitude between Buluwayo and the Cape Observatory was determined by exchange of telegraphic signals on four nights, the astronomical latitude and azimuth being also observed. After the selection of a site, a base line of $11\frac{3}{4}$ miles in length was measured, and during the year seventeen stations were occupied and measurements taken therefrom.

An arrangement for the delimitation of the Anglo-German boundary between British Bechuanaland and German South-west Africa having been approved by both Governments on January 1, Lieutenant Wettstein and Major Laffan, R.E., after some months' sojourn at the observatory for practice in astronomical observations, commenced operations at Reitfontein (long. 20° E., lat. 26° 47′ S.) on November 19, by determinations of astronomical latitude and azimuth and the selection of stations.

The existing triangulation in the Cape Colony on the meridian of 20° E. long. is at present limited to the northern triangles of Sir Thomas Maclear's arc and to Bosman's accurate triangulation of Bechuanaland from Vryburg to the 20th meridian, and along that meridian from the Orange River to Reitfontein. There thus remains to complete the chain from Cape Agulhas (the southern point of Africa) to Reitfontein, a distance of only 140 miles to be filled in. The triangles for this work have been selected, and are about to be measured with the Repsold theodolite by Mr. Alston.

In connection with the survey of Rhodesia, Mr. Rhodes has promised that when he is in a position to commence the extension of the railway from Buluwayo to the Zambesi, he will place at the disposal of Her Majesty's Astronomer the funds necessary to carry on the arc of meridian from Southern Rhodesia to Lake Tanganyika. Thus there is in prospect the completion of the following valuable geodetic data:—

(1) A geodetic arc along the meridian of 20° E. long. from Cape Agulhas (lat. 34° 49′ S.) to the parallel of 22° S. lat., perhaps to 18° S. lat., *i.e.* an arc of 12° 49′, or possibly of 16° 49′ in length.

(2) An arc along the meridian of 30° E. long. from the south of Rhodesia (lat. 22° S.) to the southern extremity of Lake Tanganyika (lat. 8° 40′ S.), an arc of 13° 33′ in length. Both of these important operations will be under the direction of Her Majesty's Astronomer.

It is also hoped that the German Government will carry the latter work along the eastern border of Lake Tanganyika to Uganda, whence the way is now clear for a triangulation along the Nile to Alexandria, *i.e.* practically along the same meridian as above, 30° E. long. This latter work should for various reasons be commenced at its northern extremity.

*Longitude of Lake Nyassa.*—The longitude of Nkata Bay

on Lake Nyassa was determined by exchanges of signals between this station and the Observatory, made by Captain Close, R.E., and Dr. E. Kohlschutter. The adopted value for the longitude of the station occupied (which was 5·2s. west of the Bay) was

2h. 17m. 7·6s. E.,

and thus the previously accepted longitude was about six miles in error. This work was undertaken in connection with the delimitation of the Anglo-German boundary between Lakes Nyassa and Tanganyika.

*Longitude of Umtali.*—Similar operations undertaken by Captain Watherstone, R.E., in connection with the Anglo-Portuguese Barué Delimitation Commission, gave the longitude of Umtali as 2h. 10m. 41·2s. E.

*Time Service.*—The usual distribution of time signals for commercial and navigation purposes has been carried out.

## PROF. F. OMORI ON EARTHQUAKE-MOTION.

THREE important memoirs have recently been published by Dr. F. Omori, Professor of Seismology at the Imperial University of Tokio.[1] In the first he describes a form of horizontal pendulum adapted for mechanical registration, a method which, like the Italian seismologists, he prefers on account of its cheapness and the more open diagrams which it provides. The pendulum consists of a thin brass cylinder, filled with lead, and weighing about 14 kg. This is attached to a horizontal tubular strut of iron, which ends in a sharp conical steel point, working in a conical steel socket fixed to the wall of an earthquake-proof house. A fine steel wire connects the heavy-bob with a triangular steel prism, whose knife-edge works in a steel V-groove mounted on a projection from the upper part of the wall. The vertical distance between the points of suspension and support is 2½ metres, the horizontal distance being, as usual, very small. The length of the strut from its pivot to the axis of the cylinder is one metre. The complete period of vibration is at present 28 seconds in one pendulum, and 17 seconds in the other. The record is made by a light pointer, connected at one end with the cylinder and turning about a vertical axis working in a stirrup rigidly connected with the ground. At the end of the long arm is hinged a light triangular writing index, the point of which rests on smoked smooth paper, which is wrapped round a light wooden drum, 942 mm. in circumference, and revolving once an hour. While the Italian seismologists endeavour, as a rule, to render their instruments sensitive by using a heavy steady mass, Prof. Omori attains the same end by reducing the friction between the parts of the machine; for instance, the pressure of the writing index on the smoked paper is only ⅝ mgm. Prof. Omori also describes a portable form of the pendulum, in which the dimensions and heavy mass are smaller, and the points of suspension and support are connected with a cast-iron stand. The paper is illustrated by some interesting typical diagrams given by the pendulums of pulsatory oscillations and earthquake disturbances of neighbouring and distant origin.

It is well known that most earthquakes begin with a preliminary tremor, consisting of vibrations whose amplitude is very small and whose period is generally very short. When the origin of the earthquake is distant, the duration of the tremors, as noticed by Prof. Milne and others, increases with the distance of the observing station; and a similar relation, as Prof Omori points out in his second paper, is evident from an examination of different seismograms obtained in Japan. He shows that the duration of the preliminary tremor does not depend on the magnitude of the disturbed area of the earthquake, for no difference of this kind is to be seen between the disastrous Mino-Owari earthquake of 1891 and its five strongest after-shocks. He finds, moreover, that, for great earthquakes originating at distances between 100 and 1000 km., the duration increases by 15 seconds for every increase of 100 km. in the distance from the origin. The duration of the tremor being ascertained at two or more stations, it is thus possible to determine the position of the epicentre; and, in two cases which are given the results agree closely with those obtained from isoseismal lines. Prof. Omori remarks that the approximate variation of the duration of the early tremors with the distance from the origin can be explained by assuming the existence of two sets of waves, which, starting simultaneously, are propagated with different velocities. The mean velocities for the Mino-Owari earthquake of 1891 and the Hokkaido earthquake of 1894 are 2·2 km. per sec. for the preliminary tremors and 1·7 km. per sec. for the principal waves.

The third paper, written in conjunction with Mr. K. Hirata, is a valuable discussion of the earthquake measurements made at Miyako from June 1896 to June 1898. The observatory, which contains a Gray-Milne seismograph, is situated on a small promontory of palæozoic rocks (in lat. 39° 38′ N. and long. 141° 59′ E.), and the records may therefore be regarded as good illustrations of earthquake measurements in a rocky district. Of the twenty-five earthquakes which form the principal subjects of the discussion, six originated in the mountainous regions to the west, and the remaining nineteen under the Pacific Ocean, the point one degree east of Miyako being the most active centre of the earthquakes which disturb the eastern part of Northern Japan. The authors arrive at the following important conclusions. As a general rule, the duration of an earthquake seems to vary directly as the magnitude of the disturbed area and inversely as the distance of the observing station from the origin. The average duration of the vertical component is about four-fifths that of the horizontal component. The period of the maximum movement, both horizontal and vertical, ranges between 0·53 and 1·7 seconds for slow undulations, and between 0·12 and 0·15 second for ripples. The average period of the horizontal slow undulations is approximately constant in the principal and end portions of an earthquake, while that of the ripples is slightly greater during the principal portion than during the preliminary tremors and end portion. It is remarkable that the average period of ripples is roughly constant in all the earthquakes here considered, never varying much from one-tenth of a second. The range of the vertical motion was invariably less than that of the corresponding horizontal motion, the maximum vertical motion being on an average one-fifth of the maximum horizontal motion; and this is true both for ripples and slow undulations. The direction of the maximum earthquake movement, as a rule, is coincident with the direction of the line joining the observing station to the centre. In two earthquakes (those of February 7 and April 30, 1897), the angle of emergence can be ascertained as well as the position of the epicentre, and from these data the focal depths are found to be 15 and 9 km. respectively.

Univ., Tokio*, vol. xi. 1899, pp. 121–145; (2) "Note on the preliminary tremor of earthquake-motion": *ibid.*, pp. 147–159; (3) "Earthquake measurement at Miyako": *ibid.*, pp. 161–195.

## UNIVERSITY AND EDUCATIONAL INTELLIGENCE

MR. A. W. BRIGHTMORE has been appointed professor of engineering construction and surveying at the Royal Indian Engineering College, Cooper's Hill.

ALL particulars referring to the technological examinations conducted by the City and Guilds of London Institute, and the regulations for the registration and inspection of classes in technology and manual training, will be found in the official "Programme" just published by Messrs. Whittaker and Co. The syllabuses of the seventy different subjects, with the list of works of reference in each, and the examination papers set this year, should prove of service both to teachers and students of technology.

THE ninth summer meeting of University Extension Students in Oxford terminated on Wednesday, August 24. The meeting was throughout uniformly successful. It was divided, as usual, into two parts, the first part terminating on August 9. The number of visitors to the meeting amounted to about 1000. Of these considerably over 100 came from Germany and the United States, other nationalities being fairly well represented. The historical period selected for study was the nineteenth century from 1837, and the scientific section of the meeting was therefore necessarily occupied with the more important results obtained during that period. The lectures were well attended and excited considerable interest. In Part I., Prof. Gotch gave two lectures on "The physiology of sensation," Mr. G. C. Bourne two on "The growth of the living organism," and Prof. H. A.

Miers one on "The growth of a crystal." Mr. H. N. Dickson lectured on the "Influence of climate," and Prof. W. J. Sollas on the "Geology of Oxford." In Part II., considerably more attention was devoted to scientific subjects. Prof. W. J. Sollas conducted a series of geological classes and excursions, and Mr. A. W. Brown gave a course of practical instruction in illustration of Mr. G. C. Bourne's lectures in Part I. Dr. Farrar gave two lectures on "Prehistoric man." Two of the evening lectures were devoted to science, Dr. A. Ransome, F.R.S., discussing microbes and disease, and Mr. G. J. Burch "Wireless telegraphy." Both lectures were admirably illustrated.

THE following important announcement is inserted in the new Directory (1899) of the Department of Science and Art:—"The Lords of the Committee of Council on Education have under consideration the assessment of the efficiency of instruction in the elementary stage of science and art subjects by inspection only. It is proposed to discontinue examinations, as a test for the purposes of assessing the grant in that stage, after the year 1900. It is proposed that papers shall continue to be set in that stage for students who may desire to be examined and to possess a certificate of having passed the examination; but that in those cases a fee should be charged to cover the cost of examination." The Directory contains a number of new regulations affecting schools and classes connected with the Department of Science and Art. The object of most of the changes is evidently to encourage practical instruction in science. Visits of students to galleries, museums, and other public institutions, or attendance at field classes, may now be registered as attendances for grants. Theoretical mechanics and Section I. of the elementary stage of physiography have been added to the list of subjects in which grants for practical work may be given. The syllabuses of inorganic chemistry (theoretical) elementary stage and of theoretical and practical metallurgy have been revised, and slight modifications have been made in connection with the syllabuses of mathematics (Stage I.) and botany. With regard to schools of science, students under twelve years of age are to be excluded from them unless specially allowed by the inspector, and students at such schools are not as a rule to be admitted to the science and art examinations. Suggested laboratory arrangements for practical work in physics and biological subjects are described in the Directory, and should be of service in connection with the construction of small laboratories.

## *SCIENTIFIC SERIAL.*

THE second part of the *Zeitschrift für Wissenschaftliche Zoologie* for 1899 contains two important contributions to the morphology of Invertebrates. The first, by Dr. P. Obst, discusses the fate of the nucleolus in the development of the ovum of certain Molluscs and Arachnids; while the second, by Dr. E. Zander, deals with the abdominal bristle-like apparatus of the Hymenoptera. Especial interest attaches to the latter communication from the author's discovery that the first formation of the abdominal appendages and of the accessory sexual organs (gonapophyses) belongs to two distinct periods of development. The first of these are truly embryological, making their appearance during ovular development, whereas the second do not commence till an early larval stage is attained.

## *SOCIETIES AND ACADEMIES.*

### PARIS.

**Academy of Sciences**, August 21.—M. Maurice Lévy in the chair.—The Perpetual Secretary announced to the Academy the loss it had sustained by the deaths of MM. Frankland and Bunsen, Foreign Associates of the Academy.—On the cause of the persistent luminous trains which accompany certain shooting stars, by M. Ch. André. Remarks on an observation by MM. Lagrula and Luizet of one of the Perseids seen on August 12; the luminous streak of the meteor could be seen for twenty minutes, during which time marked changes of form were obvious in the trail of the meteor.—On an infinite continuous group of transformation of contact between right lines and spheres, by M. E. O. Lovett.—A method for determining the Newtonian constant, by M. G. K. Burgess. The Cavendish method is modified by supporting the weight carried by the torsion thread in a bath of mercury. In this way it was possible to suspend a mass of lead of two kilograms each on a torsion wire of bronze or platinum of 0·05 mm. diameter. The sensibility of this apparatus is very great, a shifting of the large masses (10 kgr. each) through 40° turning the torsion system through about 12°. The chief difficulties would appear to be the necessity of keeping the temperature of the mercury absolutely constant, and the variations introduced by fluctuations in the surface-tension of the mercury.—On the magnetic properties of iron at low temperatures, by M. Georges Claude. The hysteresis and permeability of iron are both practically constant over the temperature-range, +25° C. to −185° C., the permeability at −185° C. being only 2·5 per cent. less than at 25° C. These results are in agreement with the experiments of Thiessen, carried out at temperatures of −80°, but are in opposition to the results of Dewar and Fleming.—Decomposition of phosphate of manganese by water at 0° and 100° C., by M. Georges Viard.—On the persistence of the cardiac contractions in the phenomena of regression in the Tunicates, by M. Antoine Pizon.—On temperature and its variations in free air, from observations in ninety captive balloons, by M. L. Teisserenc de Bort. The temperature at different heights presents in the course of the year variations much more considerable than had been supposed from the observations made in an ordinary balloon. Even as high as 10,000 metres there is a marked tendency to an annual variation of temperature.

THURSDAY, SEPTEMBER 7, 1899.

## THE LITTLE NEGROES OF THE EAST.

*The Negritos: the Distribution of the Negritos in the Philippine Islands and Elsewhere.* By A. B. Meyer. Pp. 92. (Dresden: Stengel and Co.)

DR. A. B. MEYER, the distinguished Director of the Royal Zoological, Anthropological and Ethnographical Museum at Dresden, has issued as a separate volume a translation of two chapters, brought up to date, of his sumptuous folio monograph "Die Philippinen: II. Negritos" (1893). The Negritos of the Philippines are a dwarf,[1] frizzly-haired people with a black or dull copper-coloured skin. The head is on the lower limit of brachycephaly (average index about 80). The forehead is retreating, the concave nose is broad and flat, the projecting jaw is provided with thick lips and prominent teeth. The slender body is almost entirely smooth. They are a happy, lively people to whom care seems a stranger, their greatest anxiety being the procuring of food, which consists of all things edible—fruits, roots, honey, snakes, &c. When they have provided for their wants they care for no further exertion, and love to lie in laziness and ease. Their intelligence is stated to be of a low type, and they are not able to count above five. Their songs consist of monotonous, endless unison chants. Tattooing is apparently universal, the patterns being quite simple. They are without exception monogamists.

There is no doubt that these interesting little people, about whom much more information is greatly needed, are closely allied to the pygmy blacks of the Malay Peninsula and to those of the Andaman Islands. They represent an ancient race of mankind, and thus it is important to trace their present and past geographical distribution. The name of "Aëta," "Aita," "Ita," &c., generally applied to these people, is derived from the Tagal adjective *ita*, *itim* "black" (Malay, *itam*); they were known to the Chinese under the name of "Hai-tan" at the beginning of the thirteenth century.

The headquarters of the Negritos are the island of Luzon and the small islands in its immediate vicinity; here many have crossed with the Tagals, and constitute a half-bred population called Dumagates. There can be little doubt that they are the true aborigines of the Philippines. It may be taken as certain that Negritos are found, not only in Luzon, but also in Panay, Negros, Cebu, North-east Mindanao, and Palawan, not to mention smaller neighbouring islands. It is questionable whether they occur in Guimaras, Bohol, Samar, Mindoro, and the Calamianes.

There has been much speculation on slender data concerning the distribution of the Eastern pygmy negros, of which, as we have seen, the Semangs and allied tribes of the Malay Peninsula, the Andamanese and the Aëtas form distinct groups. De Quatrefages, for example, held that traces of Negritos are found nearly everywhere from India to Japan and New Guinea, and that Negritos and Papuans live together in New Guinea, crossed and intermixed ("Négrito-Papous"), differing from the true Papuans. Dr. Meyer submits these assertions to a careful criticism, which is a valuable corrective to specious generalisation.

Theoretically, one would expect to find Negritos in Borneo; the only evidence is the account of a similar people given by Captain Brownrigg to Mr. Earl in 1845 of his shipwreck during the previous year on the east coast of Borneo, and a decorated skull described by de Quatrefages and Hamy in "Crania Ethnica." The district visited by the Captain has not been properly explored, and till that is done the question must remain in abeyance. No other white man has seen a Negrito in Borneo, and it is certain that none have been heard of in Sarawak; Mr. Charles Hose, who probably knows more about the natives of the interior than any one else, disbelieves in their existence. I have myself seen low-caste natives in the interior of the Baram district of Sarawak, whose hair was wavy and almost curly; the contrast between these and their nearly straight-haired companions could easily lead to exaggeration, but this does not necessarily indicate Negrito blood. Dr. Meyer discusses the *provenance* of the decorated skulls from Borneo in European museums; at present our information is too meagre for accurate generalisation. There appears to be no evidence that the skull in question came from the "interior of Borneo," and it is by no means incredible that the skull, or the person when alive, was imported into Borneo; slaves have probably been imported at different times, and we know that various peoples have migrated into Borneo from all quarters.

There is no evidence of Negritos in Celebes, Timor, the Moluccas and Lesser Sunda Islands. The same applies to Java (the Kalangs are not Negritos); but in Sumatra and the neighbouring islands there is still some doubt whether such a population once existed. There is less evidence for an early Negrito stock in Formosa, Japan and China. The evidence for the Mergui Archipelago is doubtful, and that for the Nicobar Islands is more so. More evidence is required for Annam, Cochin China, and Cambodia.

A good deal has been written about the occurrence of a short, dark, frizzly-haired people in India, but of these there is no evidence whatever. Curly hair is characteristic of the "Dravidian" peoples, but this is never woolly. Prof. Keane figures[1] a "Panyan woman" as a "Negrito type, India"; but a reference to the original photograph published by Thurston[2] will prove that the hair is distinctly curly, which feature is unfortunately lost in Keane's reproduction. Thurston[3] gives the average height of twenty-five Paniyan men as 1·574 m. (5 feet 2 inches), with a cephalic index of 74; these are not Negritos.

The affinities of the Australians, more or less, with the "Dravidians" is now generally accepted, but a Negrito element has not yet been proved for them. Some hold that the Tasmanians belonged to that stock, and in his

[1] Average height for males 1442 mm., 4 ft. 8¾ in.; for females 1385 mm., 4 ft. 6½ in.

[1] "Man Past and Present," 1899, Pl. II. Fig. 3.
[2] *Bulletin* Madras Govt. Mus., 1897, ii. Pl. X.
[3] *Loc. cit.*, p. 29.

recent presidential address to Section F of the Australasian Association for the Advancement of Science, "On the Origin of the Aborigines of Tasmania and Australia," Mr. A. W. Howitt believes that

"the Tasmanians were the autochthonous inhabitants of Australia, and that their preservation in Tasmania was due to isolation by the formation of Bass Strait. The occupation of the continent by the Australians who, it may be reasonably held, were in a higher state of culture, must have resulted in the amalgamation of the two races, or by the extirpation of the former inhabitants, so far at least as regards the males."

He also suggests that a later wave of Papuan migration was virtually stopped by Torres Straits. He also puts forward

"the following tentative hypothesis: An original Negrito population, as represented by the wild tribes of Malaysia; a subsequent offshoot represented by the Andamanese and Tasmanians, and another offshoot in a higher state of culture originating the Melanesians."

Whatever Mr. Howitt writes is worthy of the careful attention of anthropologists, and it would be well to direct future research with this hypothesis well in view. As Garson, Ling Roth and others have expressed the opinion that the Tasmanians were of Negrito origin (using that term in a general sense), it is rather a pity that Dr. Meyer has not discussed this point.

Finally Meyer discusses the relationship of the Negritos to the natives of New Guinea; he, with Micluko-Maclay, asserts the unity of origin of the Negritos and Papuans, and at the same time insists that the Papuans are diversified and show various types.

"Does it point to a crossing of different elements, or does it simply reveal the variability of the race? I [Meyer] incline to the latter assumption as the simplest and as provisionally sufficient, particularly as in the still so limited state of our knowledge it will be labour lost to try to resolve a race like the Papuan into its various elements."

This is not the place to enter into a discussion on this difficult problem; for the present I can only say that I am inclined to adopt the former view. I certainly have not seen or heard of any trace of Negritos as such, the brachycephals I encountered in New Guinea were no shorter than the dolichocephals, nor had they more Negritic affinities than the latter. Meyer makes the following emphatic statement:

"A Negritic race side by side with the Papuan race nobody has been able to discover, just because it does not exist, and it does not exist because the Papuan race, in spite of its variability, is on the one hand a uniform race, and on the other as good as identical with the Negritos."

A careful perusal of Dr. Meyer's critical study leaves one fact strongly imprinted on the mind, and that is the urgent need for further evidence. There can be no doubt that observation in the field is by far the most important branch of anthropological work at the present time, and all our energies should be employed in this direction. The time is fast approaching when it will be too late.

A. C. HADDON.

## BACTERIA.

*Bacteria; especially as they are related to the Economy of Nature, to Industrial Processes, and to the Public Health.* By George Newman, M.D., F.R.S. (Edin.), D.P.H. (Camb.), &c. Pp. xvi + 351. (London: John Murray, 1899.)

THE author in his preface says that the book is "an attempt, in response to the editor (F. E. Beddard, F.R.S.) of the series (the Progressive Science Series), to set forth a popular statement of our present knowledge of bacteria." "Popular science," continues the author, "is a somewhat dangerous quantity with which to deal. On the one hand it may become too popular, on the other too technical. It is difficult to escape the Scylla and Charybdis in such a voyage."

It may be said at the outset that Dr. Newman has accomplished a very difficult task in a manner which does him credit. Nevertheless, it is to be hoped that in future editions the writer will judiciously curtail certain sections and expand others, and will exercise more caution in laying down doctrines which, in some cases, might mislead the lay reader, and which occasionally even show a wrong conception of the present state of our bacteriological knowledge. That a further edition will be called for at no distant date need hardly be doubted, considering the general excellence of the work.

The first thirty-eight pages deal with the biology of bacteria. This portion of the book might well be curtailed; it contains little information that is new, and much that is old and contained in every text-book of bacteriology.

The second chapter deals with the bacteria in water, and includes much valuable information. It contains a useful reference to *B. enteritidis sporogenes* (Klein), a virulent anærobe apparently causally related to diarrhœa. The biological treatment of sewage might usefully have been discussed more fully and in a separate chapter. The statement, "The cultivation beds also have an inimical effect upon infective bacteria. Hence the final effluent is practically germ-free as regards pathogenic organisms," must be accepted with caution.

The chapter on bacteria in the air is well and concisely written, but the author quotes an experiment of his own which is a little difficult of comprehension. To quote his own words:

"The writer recently obtained some virulent typhoid excrement, and placed it in a shallow glass vessel under a bell-jar, with similar vessels of sterilised milk and of water, all at blood heat. So long as the excrement remained moist, even though it soon lost its more or less fluid consistence, the milk and water remained uninfected. But when the excrement was completely dried it required but a few hours to reveal typhoid bacilli in the more absorptive fluid, milk, and at a later stage the water also showed clear signs of pollution."

Shattock's interesting experiments are quoted, showing that sewer air does not necessarily exalt the virulence of a strain of lowly virulent diphtheria bacilli. It is to be noted that this does not affect the question of the possibility of sewer air depressing the vitality of the individual, and so allowing lowly virulent bacilli, either already present in the throat or subsequently gaining entrance, to develop and display their full power of pathogenicity.

The chapter on fermentation is a good one and is

more in touch with the original scope of the work as outlined by Dr. Newman himself in the preface. Moreover, there is much that is suggestive to the mind of the bacteriologist seeking for new avenues of research in a most important and imperfectly explored field.

The subject of bacteria in the soil is well dealt with in Chapter v., and the author records some of his own interesting experiments on nitrogen-fixing bacteria.

Chapters vi., vii. and viii. treat respectively of bacteria in milk, milk products and other foods; the question of immunity and antitoxins; and bacteria and disease. There is much in these chapters which will repay careful perusal. Dr. Newman very properly draws attention to Dr. D. S. Davies' persevering and instructive investigation of the late epidemic of typhoid fever at Bristol. It is a little difficult to measure the author's meaning when he says:

"Though the typhoid bacillus appears not to have the power of multiplying in milk, it has the faculty of existing and thriving in milk."

Dr. Newman states that the cause of scarlet fever is unknown. Perhaps it would be fairer to say that some bacteriologists consider that the proof that Klein's streptococcus is the causal agent rests on insufficient grounds.

The last chapter is devoted to disinfection, and the subject is well treated.

The book is rendered attractive with twenty-four good micro-photographs. There are seventy other illustrations; many of these are, as the author admits, diagrammatic. In a future edition some, at all events, of these might be usefully replaced by micro-photographs.

In conclusion, it may be said that Dr. Newman has successfully accomplished a very difficult task. It is true that the author has not altogether fulfilled his original intention of eliminating technical matters, and that exception may be taken to certain statements as being too dogmatic to please the cautious reader and thinker. Yet, judging the book as a whole, it may be said that it is certain to enhance the writer's reputation, and will surely be welcomed by the numerous readers of the publications of the Progressive Science Series. It is to be hoped that a demand for this volume may speedily call for a second edition.

A. C. HOUSTON.

## OUR BOOK SHELF.

*Leitfaden der Kartenentwurfslehre.* Von Prof. Dr. Karl Zöppritz. Second edition. By Dr. Alois Bludau. Erster Theil. *Die Projektionslehre.* Pp. x + 178. (Leipzig: Teubner, 1899.)

DR. BLUDAU, who has devoted much attention to map-projections, and has written some noteworthy papers on the subject, has lately published the first part of his new edition of the well-known work on cartography by Karl Zöppritz. The book has been thoroughly revised and recast; and the additional matter is so large as to render publication in two parts, issued separately, desirable. The first part deals only with the various projections of portions of the sphere that have from time to time been proposed. Dr. Bludau's object has been to produce a work which should meet the requirements of the present day, and be of real service to cartographers. With this view those projections which are of practical use are fully described, whilst those that may be termed "fancy" projections are only briefly discussed. Every effort has been made to ensure clearness and distinctness, and only those mathematical propositions and formulæ that are absolutely requisite are given. Dr. Bludau has successfully carried out his programme. The book is well written, and will be of great value and assistance to those who are practically engaged in the production of maps. Every important projection is mentioned with its date and the name of its author; and full use has been made of the researches of Tissot, and the published works of Profs. Fiorini of Bologna, Hammer and others. Dr. Bludau gives a list of the authorities whose writings he has consulted, and it may be noted that it does not include the name of any Englishman. The subject has been much neglected in this country, and nothing of any importance has been published since the papers of Airy and Clarke, and the well-known little book on the construction of maps by Hughes, the last edition of which appeared in 1864. Dr. Bludau gives almost without alteration the useful hints on drawing which appeared in the original "Leitfaden" of Zöppritz; and there are some tables for the construction of projections. Part ii. is to deal with topography and cartometry, and to contain a number of additional tables.

C. W. WILSON.

*The Dog, its External and Internal Organisation.* Edited by A. C. Piesse, M.R.C.V.S.; with Anatomical Description by W. S. Furneaux. With five plates and text cuts. Pp. 31. (London and Liverpool: G. Philip and Son.)

THIS is an oblong work of 28 pp. of the puzzle-book order, with five plates, the parts of which are cut out and so arranged in super-position that the reader first skins his dog and then works through its skeletal, circulatory, and muscular apparatus and viscera, until a median longitudinal section is reached. The latter is conspicuous for the delineation *in situ* of the central nervous system, but the entire peripheral system has been mysteriously overlooked.

The first 14 pp. of the text are devoted to a consideration of the history of the dog and of the leading breeds, illustrated by six woodcuts, the remaining 14 pp. to a so-called "Anatomical Description"—in reality an attempt at a general *résumé* of the anatomy and physiology of the vertebrate organism with especial reference to the dog, the whole concluding with a detailed explanation of the plates, the organs and structures represented being indicated by numbers. The work is of too thin and amateurish a character to merit detailed comment in these pages, but while fairly trustworthy so far as it goes, it is wanting in balance and accuracy of detail; and in attempting to express scientific facts in non-scientific terms the authors at times lapse into a looseness of expression apt to mislead.

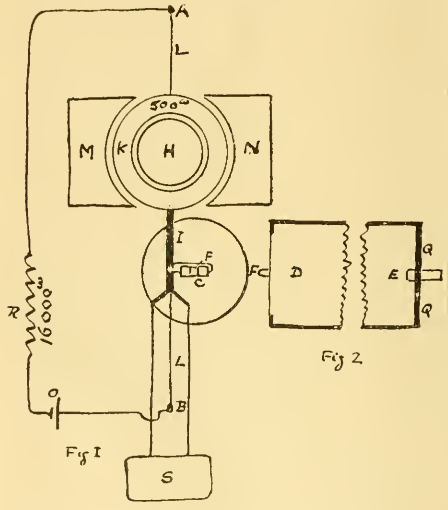
To define the "Dogs (*Canina*)" as belonging "to the family of Mammalia," and to indulge in feebly stated generalities about the structure of ganglia and the orders of nerve-fibres, to the exclusion of an adequate description of the course and nature of the leading nerve tracts, is but to confuse the mind. We do not know for what class of persons the book is intended. It will be useless to the serious student, and of little avail to the lay reader, as conveying an accurate idea of the most elementary facts. The small modicum of anatomy which it contains, interspersed with passing allusions to habit and to appearances indicative of disease, will doubtless be attractive to some persons, but by those who desire full information, such as can alone be of real service educationally or otherwise, access must be had to well-known authoritative works such as Ellenberger and Baume's "Anatomie des Hundes." The volume before us may perhaps do something to encourage a love of the dog and an appreciation of the beautiful in its construction, leading thus up to the study of the more directly useful; and for this reason we regret the more that a bibliographic list of the afore-mentioned authoritative treatises should not have been given. Without one the present work fails in its most useful purpose.

## *LETTERS TO THE EDITOR.*

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

### A Hertz Wave Receiver.

DURING a visit to Adelaide in December last year, I was asked to suggest some sort of apparatus whereby Hertz wave disturbances might be observed. The result may perhaps be of some interest at the present time. The spark at the oscillator was small, as only a small induction coil was available. From previous experiments made by me, I had discovered that in order to obtain great sensitiveness the distance between the poles of a Branly detector should be as small as possible; also the amount of current employed should be very small. After many experiments, I devised an apparatus in which only about 1/16 of a milliampere gave excellent results. The apparatus was simple and easily constructed. In Fig. 1, M N are the poles of the permanent magnet of a D'Arsonval galvanometer; K, its coil having a resistance of 500 ohms; H, the internal soft iron



— Hertz wave receiver —

fixed core; L L, the flat suspension wires; I, a rod of ebonite to the side of which a minute Branly receiver is attached. This forms a part of the galvanometer circuit, and moves with the coil through its angle of displacement, the ends A B of the suspension wires being fixed to the frame (not shown). The circuit included one small dry cell, O, and a non-inductive resistance of 16,000 ohms. In order that the Branly receiver C, after being made a conductor by the influence of a Hertz wave, may be restored to its condition of high resistance, it is brought up against a point F, when deflected (a side view of this is shown in Fig. 2). This point is kept in a state of vibration by means of a jet of water, thus, D E is a tube furnished with an elastic disc, to which a projection, F, is attached; a jet is so fixed at E that its discharge impinges on the centre of the disc, the jet is fixed to the tube by a bar, Q Q, the discharge is affected by the tube as a resonator, and hence F vibrates. The suspended coil, K, is furnished with a mirror and a pointer, whereby its movements are easily seen. This form of decohering instrument was used to avoid the evil effects due to electromagnetic vibrators, which act on a receiver if very sensitive. The induction wings were connected to the apparatus at A and B. On repeating the experiment at home, I found that 1/16 milliampere is by no means the smallest current that might be used; all that is required is a current sufficient to move the suspended coil. I am informed that the current used in wireless telegraphy is usually about one milliampere; it is obvious that by increasing the sensitiveness of the galvanometer a more sensitive coherer may be used. By means of a vane, S, moving in liquid the movements of the coil are damped. The cohering substance was an 8 per cent. alloy, made in the oxyhydrogen flame, and then reduced to filings in the usual way; it was found to be exceedingly sensitive, much more so than the mechanical mixture of filings of the two metals.

I made several attempts to use a sensitive galvanometer for closing the circuit; the results were unsatisfactory, the closing of the circuit was uncertain, and when it was closed the tendency to stick, due to the contacts, was a source of much trouble. It then occurred to me that the whole difficulty would be obviated by attaching the coherer to the moving axis of the galvanometer coil itself, for by this means the contact is entirely avoided, while the coherer is brought within the range of a constantly vibrating projection which causes immediate decoherence. A vibrating reed was tried as a decoherer, but abandoned owing to the trouble of feeding it with air under pressure. Another form of decohering vibrator was also tried, which consisted of a long tube, part of which was glass; each end was furnished with a tympan, one of which was placed as F and D, Fig. 2; the other tympan was led into a metal box containing an electromagnetic vibrator, the hammer of which beat upon the tympan remote from the galvanometer. The electromagnet may thus be placed at a great distance from the apparatus, while its impulses are communicated through the column of air in the tube.

Since my return home, I have used the Wehnelt circuit breaker for producing Hertz waves with ordinary oscillators; the effects appear to be perfect, although the space at my disposal, about two miles, is for the most part covered with houses and high buildings. F. J. JERVIS-SMITH.

Oxford, August 26.

### Is Insusceptibility to Vaccine produced by Small-pox?

IF vaccination inhibits, arrests, modifies, or mitigates variola because it is one with variola, if the attenuated virus and local eruption interfere with the more virulent and generalised eruption, may not a reciprocal antagonism be expected? If the minor malady interfere with the major malady, how much more should the major malady, within a reasonable period of years, confer some degree or manner of general constitutional protection in respect of the minor, if not a modification of the local result of vaccination? If I mistake not, systematic investigation on this point, on the human subject, has been strangely neglected in England, if not elsewhere.

CHARLES G. STUART-MENTEATH.

23 Upper Bedford Place, W.C., August 14.

SMALL-POX does leave behind it an insusceptibility to vaccinia. If the writer of the letter will refer to Dr. Monckton Copeman's article on "Variola and Vaccinia, their Manifestations and Inter-relations in the Lower Animals: a Comparative Study" (*Journ. of Path. and Bact.*, vol. ii., 1894, p. 408, *et seq.*), he will find references to the protection conferred by variola against vaccinia. That systematic investigation has not been carried out is probably due to the fact that the subject has so little practical interest.

From the point of view of those interested in the general question of immunity, this subject is well worth careful and systematic study. G. SIMS WOODHEAD.

## *THE DOVER MEETING OF THE BRITISH ASSOCIATION.*

IN addition to the arrangements described previously, an installation of Marconi's system of wireless telegraphy will be set up in the Maison Dieu Hall of the Town Hall. There will be constant communication with the South Foreland, the East Goodwin Lightship and Wimereux-Boulogne. By means of this arrangement visitors will be kept fully informed of the proceedings of the French Association at Boulogne.

In Section A (Mathematics and Physics) the President's address is intended to be taken at 10 a.m. on Thursday, September 14. On Friday, September 15, papers connected with mathematical physics and electricity will be read. On Saturday, September 16, on the occasion of the French visit, it is hoped that Prof. J. J. Thompson and Prof Oliver Lodge will communicate papers. On Monday, September 18, the section will subdivide into a meteorological and a mathematical section. On Tuesday, Prof. Threlfall will exhibit and describe his gravity metre, and a discussion on platinum thermometry will be opened by Prof. Callendar and Drs. Harker and Chappuis.

The President's address in Section B (Chemistry) will be given on Thursday, September 14, immediately after the address to Section A. It will deal with the assimilation of carbon by the higher plants, and will be mainly descriptive of new work carried out during the past two years in the Jodrell Laboratory at Kew. In addition to papers of a specially technical character several discussions of interest have been arranged for the meeting. On the occasion of the visit of the French Association on the Saturday, there will be a joint meeting of Sections B and K to discuss the question of symbiotic fermentation, both in its chemical and biological aspects. This discussion will be opened by Prof. Marshall Ward; Dr. Calmette and Prof. Armstrong, amongst others, will take part in it.

Prof. Armstrong has undertaken to open a discussion on a subject of importance and interest in organic chemistry, under the title of "Laws of substitution, especially in benzenoid compounds"; whilst a prominent place in the programme will also be given to inorganic chemistry in a discussion on "Atomic Weights," to which Prof. F. W. Clarke, of Washington, will communicate a statement of his views. Amongst the special papers already promised, Prof. Dewar hopes to be able to communicate the results of his most recent investigations on the solidification of hydrogen, and the liquefaction of helium. Prof. Ladenburg, of Breslau, will read a paper on "The development of chemistry in the last fifteen years," and Mr. H. J. H. Fenton will give an account of his recent researches on "Oxidation in the presence of iron."

In Section D (Biology) the following papers of general interest to biologists will be read, amongst others: Mr. J. J. Lister will describe a remarkable new type of calcareous sponge discovered by Dr. Willey during his expedition to New Britain. Mr. J. J. Budgett, who has just returned from the River Gambia, will give an account of the zoological results of his expedition. Messrs. Gamble and Keeble will communicate an account of their experiments on the colour changes of prawns. Prof. Poulton will describe a new series of experiments on the protective value of form and colour in insects. Mr. W. Garstang will give an account of the methods and results of a periodic survey of the plankton and physical condition of the English Channel. Dr. C. G. Petersen will describe the plaice culture in the Limfjord (Denmark). Valuable communications on special morphological problems will also be submitted. Mr. Graham Kerr will discuss the origin of the paired limbs of vertebrates; and Dr. Willey the process of cephalisation in mollusca and vertebrata. In the marine excursion, if weather permits, the plankton collecting apparatus will be demonstrated; and Dr. Petersen and Mr. Garstang will exhibit their new forms of net for opening and closing under water.

In Section E (Geography) the following papers are promised: Presidential address by Sir John Murray on the floor of the ocean; Mr. J. J. Buchanan, F.R.S., on the physical and chemical work of an Antarctic expedition; Dr. H. O. Forbes, on a visit to Sokotra; Mr. A. W. Andrews, on the use of lantern slides in geographical education; Mr. O. H. Howarth, explorations in Oaxaca, Mexico; Dr. G. Schott (Homburg) on the oceanographical work of the *Valdivia* Expedition; Mr. H. N. Dickson, on the oceanography and meteorology of the North Atlantic; Mr. H. N. Dickson will also read a paper on the temperature of the sea water round the British Islands; Sir John Farquharson, on twelve years' work of the Ordnance Survey; Mr. Vaughan Cornish, on the sand dunes of Lower Egypt; Mr. George Murray, F.R.S., on the distribution of plants in the oceans; Mr. Robert Irvine, on the distribution of nitrogen in the sea; Mr. C. W. Andrews, on oceanic islands; Sir John Murray and Mr. F. Pullar, on the bathymetrical survey of the Scottish Lakes; Mr. W. R. Rickmens, on a journey in Transcaucasia; Dr. H. R. Mill, on the terminology of the forms of ocean floor; and Mr. E. Heawood on the discovery of Australia.

In Section H (Anthropology) the President will deliver his address on Thursday morning at eleven, and the remainder of the day will probably be devoted to the discussion of reports and papers on physical anthropology. The subject of finger-prints as means of identification will be examined in important papers by Dr. Francis Galton, and Mr. E. R. Henry, who has used the method with success in police work in India. Other anthropometric points will be discussed by Dr. J. G. Garson. Mr. J. Gray contributes a paper on the population of East Aberdeenshire; and Mr. D. McIver on his recent work on the early inhabitants of Egypt.

Friday will be devoted to an important series of papers and exhibits arising out of Prof. Haddon's recent expedition to Torres Straits. Communications are promised from Prof. Haddon himself, and from Dr. Seligmann and Messrs. Ray and Rivers, who took part in the expedition. Some, if not all, of the archæological papers will be taken on Saturday. Monday and Tuesday will be occupied with papers on Ethnography and kindred subjects. Wednesday will, as usual, be reserved for overflows and late arrivals.

Among the reports, that on the education of defective children deserves particular notice, and those on excavations at the lake village of Glastonbury, the Roman site at Silchester, and elsewhere in this country, will afford interesting material for comparison with those of our French visitors.

The President's address in Section K (Botany) will be delivered at 10.30 on Thursday, September 14. On Friday afternoon a lecture—of a semi-popular nature—will be delivered by Mr. Harold Wager, on sexuality of the fungi. Saturday morning will be given up to a joint discussion with Section B on fermentation, which will be opened by Prof. Marshall Ward. On Saturday afternoon the members of Section K propose to have a botanical excursion to the sand dunes between Deal and Sandwich. The contributions to be made to the Section include papers on fungi by Prof. M. Ward, Prof. Potter, Mr. Wager, Dr. Darbishire and others; on physiological botany, by Mr. Francis Darwin; on latex of india-rubber, by Mr. Biffen and Mr. Barkin. Prof. Campbell contributes a paper on studies in Araceæ; and Mr. Willis deals with the morphology and life-history of the Indo-Ceylonese Podostemaceæ. Miss Sargant promises a demonstration of vermiform nuclei in the fertilised embryo-sac of *Lilium Martagon*. Prof. Bower will read a paper dealing with the sporangia of ferns. Prof. Bertrand, of Lille, communicates a paper on *Sigillaria*. Prof. Weiss sends a contribution dealing with *Lepidophloios*, and Mr. Seward and Miss Gowan deal with the botany and geology of the maiden-hair tree. There are also other papers expected on fossil botany. Mr. Lloyd Williams will give an account of further work on the Brown Algæ. There are also to be contributions to the Section on local botany and on other subjects of general botanical interest.

## THE FORECAST OF THE MONSOON.[1]

THE brief telegrams that have lately been published from India concerning the amount of rainfall have given a very uncertain note. Favourable and unfavourable accounts have followed in rapid succession, and at the moment of writing it seems doubtful whether to expect a normal amount of precipitation, or to dread a recurrence of one of those calamitous famines, which drain so severely the resources of India, and from the last of which she has barely recovered. In these circumstances, it is of more than usual interest to turn to the official forecast, to see how the causes, which in the opinion of the best-informed meteorologists affect the climate of India, are operating for and against the prospects of a successful harvest.

At the outset we meet with a grave disappointment. The Simla authorities distinctly express their inability to make a forecast, on any scientific ground, of two very important factors which affect the agricultural value of the monsoon rainfall. These are the possibility of the occurrence of a protracted break in the rainfall during the months of July and August, even after the season has opened favourably, and of an unusually early termination of the rains in the North and Central Provinces of India and in Bengal. For fifteen years the Meteorological Office has deplored the want of the necessary data that would warrant a prediction on these important topics, and there are no signs that the information will be forthcoming at an early date. As a matter of fact, the authorities go little further than an examination of the conditions under which the south-west monsoon currents will arrive on the coasts of the peninsula. It is true that the probable amount of rainfall in the various provinces of India is considered at some length, but it is expressly declared that this "forecast is a statement of probabilities, and not of certainties, and that it is liable to error from the limitation and uncertainty of part of the data on which it is based."

Similar words accompany all the forecasts that prudent men venture to make, and it must be admitted that the continual repetition is wearisome and distressing. Such a caution may be necessary, but if it produces on the mind of an impatient public the impression that little or no advance is being made in meteorology, and particularly Indian meteorology, a great injustice is done to a body of highly-skilled observers, who have not spared themselves to benefit science, to improve the lot of the agriculturist, and to strengthen the hands of the Government in dealing with a misfortune they are eager to alleviate, but powerless to avert.

But it is not difficult to see some of the reasons that compel the staff to halt at the result of this preliminary investigation. Forecasting, as understood in England, and which practically rests on the capacity of the telegraph to outrun the storm or the weather it announces, would be valueless in India. Away from the coasts and outside shipping interests, there is no necessity for daily forecasting, nor for the study of those ephemeral fluctuations which go to make up our weather. On the other hand, the meteorological conditions that result from the movement of enormous masses of the air attract greater scientific attention, owing to their periodic character and the effect likely to be produced on agriculture and the well-being of large masses of the population. It would be wrong, however, to forget that in late years, and mainly under the energetic direction of Mr. Eliot, barometric variations, however small in amount, have been studied with good effect, and have revealed the probable existence of cyclical variations which can have considerable influence in promoting or checking the general oscillatory motion of the air across the equator, to which motion the south-west and north-east monsoon winds are mainly due.

But in the forecast before us, though the variations of pressure from the normal, and the effect such fluctuations have on the local weather existing in India immediately preceding the advance of the monsoon, are treated as a factor in the problem, two other conditions have naturally great weight. These are the amount and time of occurrence of the snowfall in the mountain districts adjacent to Northern India, and the behaviour of the south-east trades in the preceding season, as investigated at Seychelles, Mauritius, the Cape of Good Hope, and the logs of ships passing over the area affected. Such latter information is of necessity incomplete, but is likely to be of great importance in proportion as it covers a larger area, for the greater the district brought under review, the greater the probability of tracing the true physical cause on which important variations rest. It may not be out of place, as showing the wide extent over which meteorological phenomena extend themselves, and the consequent necessity for the examination of all remote causes to which they may be traced, to recall the apparent connection existing between the barometric oscillations in the Indo-Malayan region on the one hand, and Russia and Siberia on the other. Further, we have some evidence of connection between the south-east rains of South Africa and the amount of the rainfall at the time of the summer monsoon, while the overflow of the Nile seems to participate in similar periodic variations. Such general disturbance tends to point to a common cause, and it is gratifying to know that the possibility of the connection has been pointed out by the Indian meteorological officers, who are fully alive to the importance of discovering the origin of these effects, which demonstrate themselves periodically. In basing the forecast on more or less local appearances, we seem to recognise the weak point in long-period forecasting. We are in the position of a physician who deals with the symptoms rather than the origin of a disease.

This difficulty of trusting to appearances may be illustrated in many ways. For instance, how are we going to estimate the relative importance of the two operating factors we have mentioned above, the snowfall on the Himalayas and the behaviour of the south-east trades? And how are we going to act if we find the indications from the two sources discordant? Some time since we believe that the snowfall was regarded as the one important item in the making up of the forecast. Scanty rain was anticipated as the consequence of heavy snow, but greater experience has somewhat discredited the notion. Late snow in April or May, or the cause which produces the late snowfall, no doubt does exercise very considerable influence locally on the distribution of the monsoon winds; but when we have to deal (as already pointed out) with the effects produced by the circulation of an atmosphere covering an entire hemisphere, such local results play but an insignificant part. Nevertheless, we find Mr. Eliot, who doubtless is glad to avail himself of every source of information, carefully tabulating the time and amount of the snowfall from Afghanistan on the West to Assam in the East. But, in drawing his conclusion, he does not leave out of sight the local character of the indication, and a distinction is drawn between the conditions that should follow the reports from Western India and those received from the Eastern Himalayas. In the former case, the signs point to an early and strong monsoon with beneficial results to the utmost limits of the Punjab. The conclusions to be drawn from the accounts from the eastern portion are more uncertain both on account of deficiency in the data received and greater doubt in the interpretation of the sign, but it is expected that the rainfall in North-east India will be diminished,

[1] "Memorandum on the Snowfall in the Mountain Districts bordering Northern India, and the Abnormal Features of the Weather in India; with a Forecast of the S.W. Monsoon Rains of 1899." By John Eliot, Meteorological Reporter to the Government of India, and Director-General of Observatories in India. (Simla: June 1899.)

while heavier rain will be prevalent in the north-west. It will be interesting to compare this prediction with actual results; but at present we are more concerned to point out the care that is taken in preparing the forecast, the difficulty in the collection of exact data, and the manful determination to make the best use of all available sources.

This scrupulous care is well illustrated in the second class of information incorporated into the weather prediction, and which rests on the abnormal features of the recent meteorology of India. To discuss these with any prospect of success, it is first necessary to determine correct normals. The work that this involves can only be appreciated by those who have been actually concerned in a similar inquiry, but it is a method of investigation into which Mr. Eliot and his predecessor, Mr. Blandford, have thrown themselves with signal success. The volumes of the Indian Meteorological Memoirs bear witness to the ability and zeal with which the work has been carried on throughout some twenty-five selected observatories. We may well express the hope that so much work is now yielding abundant fruit.

## THE PRESENT POSITION OF THE INVESTIGATION OF THE MALARIAL PARASITE.

THE *rôle* played by the mosquito as a carrying agent of the malarial parasite from man to man seems to be restricted to one genus, the Anopheles. Major Ross, of the Liverpool School of Tropical Diseases, in a telegram from Sierra Leone, announces the fact that he has found the Anopheles there, and that it may be the intermediary host of the quartan malarial fever.

Many observers in different countries, noticing the fact that malaria is most prevalent at the most active period of mosquito life, have attributed malaria to the agency of this insect. Dr. Patrick Manson, in 1894, first brought the subject forward in England, and, acting on his suggestion and advice, Major Ross undertook an investigation in India.

In 1897, by using two species of Anopheles, Ross traced the malarial parasite into the wall of the stomach of the mosquito after it had fed on patients whose blood contained the crescentic gametocytes; the next year he succeeded in tracing the complete life-history of the proteosoma *Grassii Labbé* of sparrows, and showed that its intermediary host was one particular kind of mosquito, the *Culex pipiens*. The gametocytes contained in the red blood corpuscles of the vertebrate host pass with the blood into the stomach of the mosquito, and passing through the stomach-wall bulge into the body-cavity; here a sexual process takes place, zygotoblasts are eventually formed, which pass into the insects' blood, and finally find their way into the salivary gland and to the duct leading from this to the extremity of the stylet; from here they escape into the blood of the vertebrate host when the insect bites. A full account of the process is given by Ross in NATURE of August 3.

Following on these results, Grassi in Italy attacked the problem from another point of view; he studied the mosquitoes prevalent in the different parts of the country where malaria occurs. The results were interesting. He found there was no indigenous malaria where the *Culex pipiens* was common, but it did occur where the large mosquito Anopheles was found.

Bignami and Bastianelli, who had been trying unsuccessfully to infect a man by allowing mosquitoes to bite him, attributing their want of success to the use of the wrong kind of mosquito, and, acting on the observations of Grassi, tried again with some mosquitoes imported from a malarious district. This time they succeeded in infecting the man with malaria of the same type that prevailed in the district from which the mosquitoes came. Moreover, they have shown that the development of the human form of parasite in the body of Anopheles is identical with the development of the proteosoma of birds in *Culex pipiens*, as observed by Ross.

According to these observers, the species *Anopheles claviger* is the most common intermediary host of the parasite of malaria in Italy, the tertian and summer-autumn types.

It is evident that the next step in the study of malaria should be to hunt for the different species of Anopheles and see if these are the intermediary hosts of the different types of malaria throughout the world, and what particular species is most concerned in transferring the parasite from man to man. Grassi has done this for Italy, and now we hear that Ross has found a species of Anopheles to be concerned in the transference of quartan fever; thus all the types of malarial fever are now referred to the Anopheles as their intermediary host. His full report on return from Africa will be read with interest.

Whether the Anopheles can be extirpated from a locality, and by what means, will be the problem for scientific workers resident abroad to settle; fortunately they seem to be confined to small areas, so the suggestion of Ross to draw off the water from stagnant pools may not be so hopeless a task as it would at first appear.

## NOTES.

THE following men of science have been elected fellows of the Reale Accademia dei Lincei. As ordinary fellows: for mathematics, P. Tardy, G. Veronese; for mechanical science, G. Favero, G. Colombo, V. Volterra; for agricultural science, A. Targioni-Tozzetti. As corresponding fellows: for mathematics, G. Ricci; for mechanics, G. A. Maggi; for physics, G. Grassi, A. Battelli; for crystallography and mineralogy, A. D'Achiardi; for botany, F. Delpino; for agriculture, A. Borzì; for pathology, E. Marchiafava. As foreign fellows: for mathematics, G. Mittag-Leffler, J. Weingarten; for physics, E. Mascart, W. Kohlrausch; for chemistry, Ludwig Mond, E. Fischer; for crystallography and mineralogy, C. Klein, F. Fouqué, F. Zirkel; for geology and palæontology, O. Torell, A. De Lapparent, R. Lepsius; for botany, W. Pfeffer; for zoology and morphology, E. Haeckel, E. van Beneden; for physiology, E. Pflüger, E. Hering.

THE Berlin correspondent of the *Times* reports that the Imperial Government has ordered Prof. Kossel, of the Board of Health, to proceed to Lisbon and Oporto to study the plague and the methods adopted to combat it. Prof. Kossel will be accompanied by Prof. Frosch, of the Berlin Institute, for the Study of Infectious Diseases, who is being despatched on the same mission by the Prussian Government. Drs. Calmette and Salinbeni are already investigating the outbreak, and will report upon it to the Paris Pasteur Institute.

PRINCE KROPOTKIN sends us a note which suggests that the movements of sea-gulls along the British coasts may indicate forthcoming weather changes. On Saturday, August 26, while off Broadstairs, he noticed several flocks of gulls flying along the coast towards Dover. The wind was then blowing from the north-east, as it had been doing throughout August, and there was little indication of a change; but an old fisherman remarked that the gulls which had stayed on the coast at Margate and to the west of it were moving to the south coast to meet a south-west wind, which was sure to come. As is known, the change occurred on the following day, and the wind veered round to the south-west. In connection with this observation, it is worth remark that Mr. Inwards, in his "Weather Lore," says: "The arrival of sea-gulls from the Solway Firth to Holywood, Dumfriesshire, is generally followed by a high wind and heavy rain from the south-west."

THE death is announced of M. Henri Lévêque de Vilmorin, first vice-president of the Paris Société d'Horticulture, and officer of the Legion of Honour.

THE tenth annual general meeting of the Institution of Mining Engineers will be held at Sheffield on September 19-21, under the presidency of Mr. J. A. Longden. Among the subjects of papers to be read or taken as read are:—Instantaneous outbursts of fire-damp and coal at Broad Oak Colliery, by Mr. John Gerrard; Castleton: history, geology, minerals and mining, by Mr. A. H. Stokes; the Peak Cavern, by the Rev. J. M. Mello; the mining districts near Kamloops Lake, British Columbia, by Mr. G. F. Monckton; the Devonian ironores of Asturias, Spain, by Mr. J. A. Jones; alternating currents and their possible applications to mining (Part i.), by Mr. Sydney F. Walker.

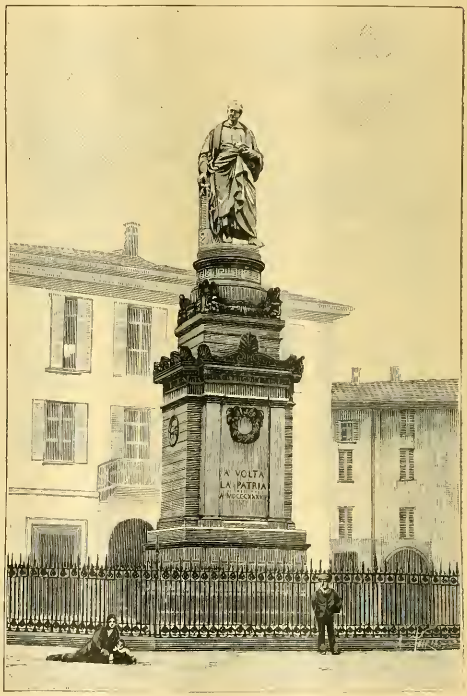
A TEACHER of science with a successful career before him has been lost by the death of Mr. O. G. Jones, who was killed in an accident on the Dent Blanche on August 30. Mr. Jones was appointed to the post of physics master in the City of London School in 1892, when a science side was being organised. He received his training at the Finsbury Technical College and at the Central Technical College, South Kensington, at both of which institutions he held scholarships. He was a B.Sc. of the University of London, where he took first class honours in physics. He possessed high qualities as a teacher, and his sad death will be much regretted.

THE New York *Nation* publishes a few particulars referring to the Danish northern lights expedition which has just left Copenhagen for Iceland. The headquarters will be at Akureyri, a prettily situated little town on Iceland's northern coast. The expedition has been for several months under preparation, and its members have been carefully practised in the use of the instruments, all of the latest construction, which it carries with it. While the headquarters will remain at Akureyri, an auxiliary station will be established on a high hill not far away, and the two stations will be connected both by telephone and by an optical telegraph. The Director of the Danish Meteorological Office, Dr. Adam Paulsen, is at the head of the expedition. He will test his own published theories on the aurora, as well as others advanced by various investigators. Among the instruments to be used are photographic ones, and others of a novel character for the measurement of aerial electricity. Dr. La Cour and Dr. Jantzen are the two chief assistants to Dr. Paulsen, while Count Harold Moltke is attached to the party as its artist. The expedition will return in May 1900.

FROM Schwaz in Tirol to Gloggnitz in Lower Austria the southern boundary of the northern Dolomites and the central zone of the Eastern Alps is marked by a distinct depression, corresponding to a band of palæozoic schists, and evidently produced by denudation. This depression may have been a longitudinal valley, perhaps even in Tertiary times, but it is now drained by five channels which have been eroded across the whole of the northern Dolomites, the valleys of the Inn, the Lake Chiem Ache, the Saalach, the Salzach, and the Enns. In a short but valuable paper, contributed to the current number of the *Mittheilungen* of the Vienna Geographical Society, Prof. C. Diener discusses the relation of each of these valleys to the structure of the rocks through which it has been cut. He finds that in their present form all five are simply results of the erosive action of running water, and their position is practically independent of the complex tectonic structure of the region.

THE scientific aspects of the question of musical pitch were described in last week's NATURE by Mr A. J. Hipkins. A book has now been published containing letters, articles, and comments which have appeared in the press with reference to the proposal to adopt the low pitch throughout the pianoforte trade. The following agreement has been signed by the leaders of the pitch movement in the pianoforte trade:—"The vexed question of a suitable pitch for pianofortes should be settled, and believing that the time has arrived when it can be done effectually, we, the undersigned, after due deliberation, have decided to adopt the Paris diapason normal, but with the allowance for a higher temperature in orchestral performance, accepted since 1896 by the Philharmonic Society—namely, A 439 (C 522) at 68° Fahrenheit. From September 1, 1899, we intend to adopt this pitch as a standard for pianofortes both for retail and wholesale purposes, and will regard the late Philharmonic pitch A 454 (C 540) when required, as an exception, and not, as has been for many years in this country, the rule."

IN commemoration of the centenary of the discovery of the galvanic pile, and in connection with the International Exposition at Como, a statue of Volta has been erected on the Piazza Volta, by public subscription. The accompanying view



of this monument to the pioneer of electrical science is given in *La Nature*. Upon the pedestal of the statue the following words appear:—

OMAGIO
DEI TELEGRAFISTI
D'OGNI NAZIONE
NEL PRIMO CENTENARIO
DELL' INVENZIONE
DELLA PILA
MDCCCXCIX.

As already announced, a National Electrical Congress will be held at Como, in connection with the Volta centenary celebra-

tions, on September 18–23. The congress is being organised by the Associazione Elettrotecnica Italiana and the Società Italiana di Fisica, and the leading foreign scientific authorities have been invited to attend.

THE report of the Director of the Botanical Survey of India, for the year 1898–99, shows that every advantage has been taken of the funds placed at the disposal of the survey for exploration in Burma, Assam and Bengal. A report by Mr. J. F. Duthie, Director of the Botanical Department of Northern India, states that the two parties of plant collectors who left Saharanpur in March 1898 to collect botanical specimens in the forest tracts of the Rohilkhand, Northern Oudh and Gorakhpur districts, collected between them about 1000 species; and also seeds of a large number of trees and shrubs for sowing in the Saharanpur Garden The collections include several very interesting plants, for many of them had not been previously recorded for that part of India, whilst some had not been collected since they were originally discovered by Buchanan-Hamilton and others many years ago.

A BLUE-BOOK just issued, on the number of persons employed, and accidents in mines and quarries in the United Kingdom in 1898 contains several noteworthy points. During the year, 990 separate fatal accidents occurred in and about the mines and quarries, causing the loss of 1075 lives. Compared with the previous year, there was a decrease of twenty-five in the number of fatal accidents and a decrease of twenty-seven in the number of lives lost. When these numbers are considered in relation to the number of persons engaged in the mining industry, it is found that the death-rate in 1898 was the lowest hitherto recorded, viz. 1·28 per thousand as compared with 1·49 for the preceding five years. The improvement commenced in 1895, and has continued steadily down to the present time. It is pointed out that the use of naked lights—always the principal source of danger—is responsible for 147 out of the 163 explosions which occurred, and for sixteen of the twenty-seven deaths. In one of the worst explosions in 1898, it was conclusively proved that the explosion was one of coal-dust alone, and that it was caused by a shot of gunpowder illegally fired in a place which was very hot and dusty. As usual, gunpowder caused far more accidents than any other explosive, and nitroglycerine compounds were responsible for more accidents than nitrate of ammonia compounds.

THE Physical Atlas which has been for about ten years in preparation at the Edinburgh Geographical Institute, under the direction of Mr. J. G. Bartholomew, will be the most comprehensive of its kind ever attempted. A draft prospectus just issued shows that the work will comprise seven volumes and more than two hundred plates. The subjects of these volumes will be geology; orography, hydrography, and oceanography; meteorology; botany; zoology; ethnography and demography; general cosmography and terrestrial magnetism. Berghaus's "Physikalischer Atlas" has been used as the basis of the undertaking; but the present work is much more extensive, and comprises entirely new and original material. Mr. Bartholomew's aim has been to produce a cartographic unification of natural science at the present time, and neither pains nor expense have been spared to make the Atlas a standard one to which men of science may turn with confidence. The meteorology section, with over 400 maps on thirty-four plates, will shortly be published.

AMONG the recent publications of the Deutsche Seewarte we would draw attention to a valuable discussion by Dr. W. Köppen, in vol. xxi. of *Aus dem Archiv*, upon recent determinations of the relation between wind velocity and Beaufort's wind-force scale (0–12). The relatively great expense of anemometers, and the difficulty of obtaining a good exposure for them, are obstacles to their general use, while the employment of the Beaufort scale is necessarily continued at the great majority of observing stations, and at sea. It is therefore important to determine satisfactorily the relation between wind velocity and force. The first serious attempt at this determination was made by Mr. R. H. Scott, in 1875, and the values then obtained still appear in text-books and instructions, although it is now admitted that the instrumental factor 3, which had hitherto been generally used for the conversion of the anemometrical records into miles per hour, is considerably too high. Since that time experiments have been made, notably by Köppen, Sprung, Mohn, Dines, Curtis and others, the general result of which has been to show that the factor in question should be reduced to about 2·2. This result is confirmed by Dr. Köppen's recent investigation, and we understand that, as a result of his inquiries, anemometrical records in all the publications of the Seewarte will in future be reduced to real velocities by this smaller factor. We recommend the careful perusal of Dr. Köppen's paper to all meteorologists.

WE have received from the Secretary to the British Association Committee on Zoological and Botanical Publication a notice to the effect that at the Bristol meeting of the Association the committee was reappointed, with the Rev. T. R. R. Stebbing as chairman, in succession to the late Sir W. H. Flower, and with the addition of Messrs. B. D. Jackson and A. C. Seward as representatives of Botany. It is now proposed to deal with botanical publications; and it is believed that the principles and proposals of the 1897 report will apply with equal force to botanical papers. It is hoped that they may be interpreted in that spirit. It will be well to remind our readers that the recommendations are as follows, viz.:—(1) "That each part of a serial publication should have the date of actual publication, as near as may be, printed on the wrapper, and, when possible, on the last sheet sent to press. (2) That authors' separate copies should be issued with the original pagination and plate-numbers clearly indicated on each page and plate, and with a reference to the original place of publication. (3) That authors' separate copies should not be distributed privately before the paper has been published in the regular manner. (4) That it is desirable to express the subject of one's paper in its title, while keeping the title as concise as possible. (5) That new species should be properly diagnosed, and figured when possible. (6) That new names should not be proposed in irrelevant footnotes or anonymous paragraphs. (7) That references to previous publications should be made fully and correctly if possible, in accordance with one of the recognised sets of rules for quotation, such as that recently adopted by the French Zoological Society."

AN account of the electric welding of tram-rail joints in the city of Buffalo, U.S.A., is given in the *Electrical Review* of August 25. This process of rail welding has been greatly improved, and the results now obtained are seemingly all that can be desired. In Buffalo the bar used for welding is $1 \times 3 \times 8$, and this joining of steel to steel, and the increased carrying capacity owing to the bars at the joints, results in a joint being a place of least resistance. The plant in operation for the purpose of welding consists of five cars. One of these is a sand-blast car which runs in advance of the welding car, and prepares the joint. The other cars are the welding car, the transformer car, the motor and booster car, and a car that follows in the rear to smooth any rough places about the joint. After the welding bars are placed over the joint the jaws of the welder are applied to them, and a pressure of about 1400 lbs. applied by means of a hydraulic jack connected to the upper

end. The current is then turned on, and the metal becomes brighter and brighter until the weld is completed, after which the current is turned off and the pressure increased to about thirty-five tons. While under this pressure the weld is allowed to cool, after which the car is moved back about six inches and the jaws applied to the other end of the bar, where the process is repeated. The other end is treated in the same manner. In other words, the centre weld is made first, and then the end welds. Artificial means of cooling are used, and as the bars cool they exert a powerful influence in bringing the rail ends close, so as to make a tight joint. The current for the operation of the plant is taken from the regular trolley wire service. It would be expected, from considerations of the action of heat upon metals, that rails welded in this way would buckle when they experienced a considerable rise of temperature, or snap when the temperature was very low, but, as a matter of fact, welded rails neither buckle nor break. By applying immense pressure to the material during welding, the length of a continuous rail made by this process is said to have no limit except that of the line itself.

DR. FRANZ BOAS has made a mathematical study (*American Anthropologist*, N.S., i. p. 448) of the biological significance of the cephalic index on the lines suggested by Mr. Francis Galton, and fully developed by Prof. Karl Pearson. His conclusion is that while the cephalic index is a convenient practical expression of the form of the head, it does not express any important anatomical relation. On the other hand, the relation between capacity and head diameters is found to be of fundamental importance, and among these the relation between the transverse diameter and capacity is most significant. Since in measurements on the living we are unable to measure capacity of the head, it is necessary to find a substitute. It would seem that circumferences are the most available means for judging cranial size. Therefore such circumferences should be included in all anthropometrical schedules designed to investigate racial characters.

FROM the Field Columbian Museum we have received Nos. 3 to 6 of the first volume of its "Geological Series" (Chicago, 1899). No. 3 treats of the ores of the South American Republic of Colombia, the specimens being described by Mr. H. W. Nichols, from a collection made by Señor F. Pereira Gamba. The ores were obtained from the mountainous western portion of Colombia, in which the Andes entering from the south divides into three chains known as the eastern, central and western Cordilleras. Gold was first mined by Europeans in Colombia in 1537, and during the sixteenth and seventeenth centuries the country was the great gold producer of the world; now it is said to rank ninth in importance. Iron ore is worked and smelted at Amagá. The authors observe that the gold and silver ores occur either in the acid lavas, which have been erupted at intervals from the close of the Tertiary period to the present time, or in adjacent Archæan schists. In the early days of mining, the superficial weathered rocks, which are the richest, were worked with signal success; the mines are now sunk below this zone. The ores are found in quartz as fissure-veins in the schists, and also as segregations from the surrounding lavas. In the latter case, they appear to have come to the surface in the lavas, from which they have to some extent been leached by hot solfataric waters and by tropical rains.

MESSRS. NEWTON AND CO. inform us that the whole of the lantern exhibitions at the forthcoming meeting of the British Association at Dover are to be carried out by them.

MESSRS. PHILIP HARRIS AND CO., Birmingham, have just published a diary which should be of service to science teachers. The diary covers the year from September 1, 1899, to August 31, 1900; and, in addition to the usual blank pages, contains seventy-six pages of tables and definitions frequently required in physical and chemical laboratories. The book is thus similar to an engineer's pocket-book, and its publication in the form of a diary will make it a constant companion of many science teachers.

MESSRS. R. FRIEDLÄNDER AND SON, Berlin, have issued in a single volume the numbers of *Naturae Novitates* published by them during 1898. It is well known to collectors of scientific books that Messrs. Friedlander's publication contains a useful classified list of current literature on all branches of science, compiled from catalogues in many languages. It is convenient to have these bibliographical lists in volume form, and a full index at the end increases their value.

THE additions to the Zoological Society's Gardens during the past week include a Sykes's Monkey (*Cercopithecus albigularis*, ♂) from South Africa, presented by Mr. W. P. Peyton; a Common Camel (*Camelus dromedarius*, ♂) from Mogador, presented by Mr. F. G. Aflalo; a Stone Curlew (*Oedicnemus scolopax*), European, presented by Mr. S. M. Sargant; a Common Raccoon (*Procyon lotor*) from Barbados, deposited.

ERRATA.—Lord Kelvin asks us to notify the following errata in the MS. of his letter on the "Blue Ray of Sunrise over Mont Blanc," published last week (p. 411):—Line 1, for 5 o'clock read 4 o'clock; line 7, after "light" insert "of sunrise."

## *OUR ASTRONOMICAL COLUMN.*

During the week the comet passes through the north-west of Andromeda, being a few degrees west of γ Andromedæ on the 11th. It is in a good position for observation, but is reported as extremely faint.

In *Popular Astronomy* (vol. vii. pp. 340–342) Prof. C. D. Perrine describes the circumstances of his rediscovery of this comet on June 11 of the present year. The observation was made in the early morning with the 36-inch Lick refractor, the atmospheric conditions being very good. The comet appeared as a round nebulous mass about 30″ in diameter, very faint and with but little central condensation. The orbit is more nearly circular than that of any other known comet, lying wholly between the orbits of Mars and Jupiter, thus suggesting a possible, but as yet unproved, connection with the asteroids also occupying that position.

THE NEW ALGOL VARIABLE IN CYGNUS.—The following are the predicted minima of this newly-discovered variable, which will admit of observation during September:—

| | | d. h. m. |
|---|---|---|
| 1899, September | ... | 12 11 58 G.M.T. |
| | | 21 15 27 |

Mr. J. A. Parkhurst gives (*Popular Astronomy*, August 1899, vol. vii. p. 380) two charts of the stars in the neighbourhood, which will greatly facilitate the detection of the variable. Observations may be satisfactorily made with telescopes of 3 inches aperture. The position is about 1° south preceding the 5th mag. star $o^1$ Cygni.

HARVARD COLLEGE OBSERVATORY.—Prof. Pickering has recently issued the second part of vol. xxiv. of *Annals of Harvard College Observatory*, containing an exhaustive discus-

sion of the observations made with the meridian photometer during the period 1882–88. The magnitudes, as given in the "Harvard Photometry," are compared with both the "Uranometria Argentina" and the *Bonn Durchmusterung*.

For the greater part there is close agreement, but the magnitudes in the *Bonn Durchmusterung* are found to have a systematic variation according to the right ascension, the stars grouped at about R.A. 7h., in the Milky Way near Monoceros, being more affected than others also in the Milky Way, but at R.A. 18–19h., in Aquila.

Part of the differences between the "Harvard Photometry" values and those of the "Uranometria Argentina" are ascribed to the difference in position of the two stations, as the zenith distances of the stars would be different, and therefore, presumably, the atmospheric absorption; no correction being applied for this, the southern stars at Cordoba would be estimated too bright.

An attempt to revise the scale of the *Durchmusterung* decided that it was practically impossible to reduce it to the photometric scale by any simple rule, and for purposes of comparison the necessary corrections are given to convert one scale into the other from magnitudes 1·0 to 9·2.

Pages 185–233 are devoted to a discussion of the relation between the magnitudes in the *Harvard Photometry* and those determined by Sir William Herschel. Of the six catalogues of Herschel's observations, the third is considered more accurate, and the fifth less so, than the others. In all he published observations of 3000 stars, and the *average* difference from the photometric catalogues of the present day is only $\pm 0{\cdot}16$ magnitude, this including both the possible change during the century which has elapsed and the errors of both determinations. Prof. Pickering is surprised that these observations should not have been repeated at intervals of ten or twenty years, so that deviations of individual stars might be detected. With this idea he gives a special table including all stars in which the difference between Herschel's magnitudes and the photometric ones equals or exceeds half a magnitude.

The remainder of the volume, pp. 234–245, deals with investigations in regard to the relative performance of the large and small meridian photometers which have been employed in the production of the *Harvard Photometry* itself. No difference exceeding the hundredth of a magnitude was detected. Tables are given showing that the values of the *Harvard Photometry* are not sensibly affected by variations of magnitude, right ascension, declination, or proximity to the Milky Way.

## TORSION-STRUCTURE IN THE ALPS.[1]

ONE of the most brilliant and suggestive chapters in Suess' monumental work "Das Antlitz der Erde" is that in which he deals with the remarkable whirl shaped arrangement of the leading lines of the Alpine system (vol. i. chap. 2).

Prof. Suess describes how the "leading line" sweeps round the north in one great curve convex to the north, the Apennines describe a curve convex towards the east, whereas the Dalmatian mountains form opposite it a curve convex to the west; and the curve of the Apennines is continued westward along the Algerian ranges of North Africa, whereas the Dalmatian curve is continued eastward towards Asia Minor. Prof. Suess points out that movements of crust-folding have always taken place towards the convex or outer side of these curves, and have in most cases caused an actual transgression of the curves above the regions in front of them. He further states that it is not fully understood why the mountain-systems should follow curved lines, or why the curves of the Alpine upheaval should in many areas repeat those of former mountain-systems.

Let me, before going further, remind the reader of a lecture given by one of the greatest of stratigraphers, Prof. Lapworth, at a meeting of the Royal Geographical Society five years ago, and reported in these pages ("The Face of the Earth," NATURE, April 26, 1894). This lecture set forth the conception of crust-torsion, demonstrating that "like the present surface of a typical geological formation . . . the surface of the earth-crust at the present day is most simply regarded as the surface of a continuous sheet which has been warped up by the two sets of undulations crossing each other at right angles. But in the case of the earth-surface, the one set of undulations ranges parallel with the equator, and the other ranges from pole to pole."

Prof. Lössen's explanation of the involved stratigraphy of the Harz mountains lays the foundation of our knowledge of torsion phenomena in the field, and, although other explanations have been given of the special difficulties in the Harz mountains, Prof. Lössen's is now generally accepted.

When working out the detailed stratigraphy of a part of the Dolomites, I experienced the same difficulties which Prof. Suess had indicated in connection with the "whirled lines" of the Alpine system generally. My results were laid before the Geological Society in December 1898, and are now published in the August issue of the *Quart. Journ. Geol. Soc.*, along with a stratigraphical map of the district examined. In that paper I have tried to show that the possible solution of some of the difficulties lies in the association of torsional movements in conflicting directions through the crust, with movements of crust-folding taking place across a pre-existing set of crust-folds. The *change in the direction of the resultant earth-thrust* is the cause to which I have ascribed the torsional phenomena observed in the crust-folds.

The following notes will indicate as briefly as possible wherein the characteristic features of Sella and Enneberg in the Dolomites are analogous with characteristic features of the Alpine system, and how far the elucidation I have offered for that area on the lines of torsion may be capable of a wider application.

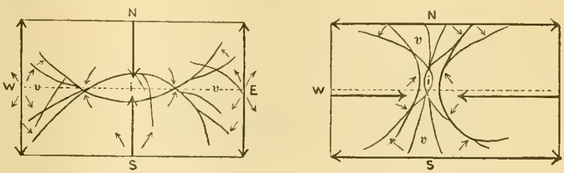

FIG. 1.—Formation of fold-arcs under the influence of torsion-forces. *i*, areas of interference; *v*, areas of virgation.

The stratigraphy of Sella and Enneberg is characterised by twisted strikes, twisted cleavages, twisted arches, twisted troughs, twisted faults, twisted dykes and sills—in fact, the rocks have been twisted and sheared to such a degree that thick deposits have been twined into the form of rock-whorls and large masses of limestone for the greater part changed to dolomite. The various combinations of twisted strikes produce the effect of "whirled" stratigraphical lines round individual centres of the region examined. Sigmoid curves in one direction are correlated with sigmoid curves in another, and arcs which are convex towards north and south are connected by virgating lines with arcs which are convex towards east and west.

Thus we may say that the curves round the north, east, and south of the Sella mountain resemble the "whirl-shaped leading lines" of the Riviera Alps, Apennines and Algerian mountains round the western basin of the Mediterranean Sea; while the curves round the north, west, and south of the Prälongia and Sett Sass area resemble the whirl-shaped lines of the Dalmatian and Pindus mountains and the curvature through the eastern basin of the Mediterranean Sea. The latter curvature resembles that of the mountains around the Roumanian plain, or of the Alps round the plain of Piedmont.

Examples might be multiplied interminably, and on great and small scale, *the reason being that the essential structure of the Alpine system is based upon spirally twisted folds, and not upon linear anticlines and synclines.*

The formation of fold-arcs is illustrated in the accompanying diagrams (Fig. 1), which show that the action of one torsion-couple must be compensated by the reverse action of a correlated torsion-couple, and a fold-arc convex towards one compass direction must be coordinated with a fold-arc convex towards the opposite compass direction. When the convexities approach one another during torsional movements the result is that oppositely-curved fold-arcs intertwine in an area which may be

[1] Condensed from the concluding chapter, "Application to the Alps," in a paper presented at the Roy. Geol. Soc., December 1898.

termed an area of "interference," to distinguish it from the areas of "virgation" where fold-arcs curve away from one another.

A fold-arc is not a homogeneous fold, but is made up of a series of unit-folds, each of which is the segmental portion of a curve. Any one fold, as it were, dies out in its particular direction and horizon, but is replaced by a fold in the next part of the curve passing through slightly different horizons of the crust. Thus the arc round which a series of unit-folds is arranged comes under the category of curves that change their plane.

In Enneberg, series of fold-arcs with their convexities towards different compass directions have been overcast, and the overcast folds have been penetrated by reverse and normal fault-planes, reverse movement having taken place in the subjacent slices of the overcast folds. But, combined with reverse movements in virtue of vertical components, there have been converse movements in virtue of torsional components, so that the actual resultant movement has been spiral—*e.g.* while the middle or "arch" slice of an overcast fold moved in clockwise direction and outward, the upper and under slices of the same fold moved in counter-clockwise direction and inward.

The problem resolves itself into involute and evolute movements of crust-slices with reference to central areas, the evolute slices tending ever to spread, the involute slices ever to narrow.

Shear-breccias and fragmentary portions of folds fill up the inwardly-tilted troughs. The fault-rocks in certain of the sheared and twisted troughs of Enneberg had been formerly treated as independent zones of rock, and termed "Buchenstein Agglomerate"; but in my paper they are shown to be practically a "Flysch conglomerate," formed during the Tertiary epoch of Alpine upheaval.

The "Flysch" troughs which appear round the Alpine curves may possibly be explained as the result of similar processes of involute and evolute movements going on in slices of closely-piled overcast folds. Thus we might have troughs being twisted inwards and gathering "Flysch" in variable fragments, while evolute slices of the reciprocal arches were being twisted outwards. The "Klippen," and even the "Klippen" ranges, may represent such "arch" wedges of fold-arcs originally closely piled and jammed as the fold-arcs are round the dolomite massives.

There is abundant evidence in Enneberg that the molten layers immediately below the crust have shared in the movements of torsional-folding. They have filled the body of the virgating fold-arcs produced by these movements, and have there been incorporated in the local crust-whirl of torsion-movements, finding inlet into the planes of fold-shearing, and being dragged and twisted along with adjacent fault-blocks. An inrush during earlier phases of torsion has been in its turn invaded by the next inrush, and so on, in accordance with the gradual progress of torsion; the latest invasions occur along transverse and oblique faults, belonging to a system of faults which has affected Oligocene strata in the Judicarian area; hence such injected rock is not older than Middle Tertiary.

The fundamental feature of torsional folding may be said to be centralisation; whether it be involution of certain horizons in covered troughs, or evolution of other horizons in overcast arches, the movements have reference to the centres of torsion-basins and torsion-buckles.

The principles thus demonstrated in Enneberg will be seen to involve the "fan-shaped structure" of central massives. They could not fail to do so, since they have been deduced from the stratigraphy of Sella massive in Enneberg, which presents a wonderfully symmetrical, although obliquely elongated example of "fan-structure."

I have shown in my paper on Enneberg that the transverse faults define a later or Tertiary series of arches and troughs, through whose septal portions they chiefly pass. The faults are shearing-planes, and are the result of oppositely-directed movements of twisting and thrusting which have taken place from opposite arches upon common reciprocals, the intermediate troughs. These movements have produced the virgating groups of north and south fold-arcs which meet the east and west fold-arcs, and the sigmoidal combinations of torsional fold-arcs and fault-curves represented in Fig. 2.

The continuance of the faulting during a protracted period of crust-adjustment has caused displacement of the arcs on the opposite sides.

There are several well-known lines of tranverse and oblique shearing through the Alps which repeat these phenomena on a larger scale, and at the same time no detail is wanting in the comparison. Some of these may be indicated: (1) The Judicarian-fault; (2) Iseo-Ortler; (3) Como-Sonthofen; (4) Maggiore-Sargans; (5) Tarentaise-Thun; (6) Savoy-Freyburg—all these represent directions of inthrow and faulting along the "septum" or "middle limb" between great transverse arches and troughs which form part of major Alpine torsion-curves.

With regard to the eastern Alps, there are also well-marked N.N.E.-S.S.W. directions of faulting and displacement. The pre-eminent example is the remarkable series of down-throws at the eastern limit of the Alps, with which is associated the displacement of the northern curve of the Alps towards the Carpathian curve. At the same time, the influence of the co-ordinated torsional movements round the Hungarian basin is evidenced in the eastern Alps by N.N.W.-S.S.E. directions of transverse-shearing.

All the transverse directions of tectonic disturbance in the Alps have in common with the parallel Enneberg lines (*a*) the

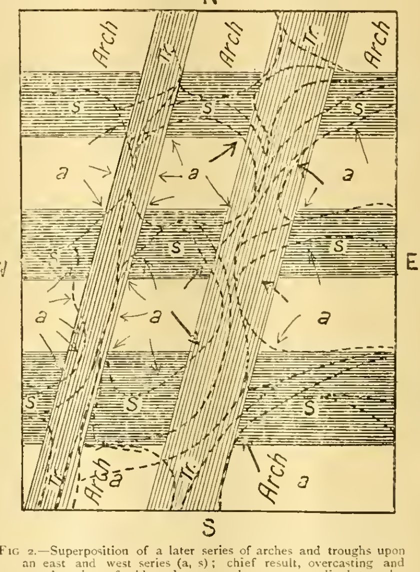

FIG. 2.—Superposition of a later series of arches and troughs upon an east and west series (a, s); chief result, overcasting and overthrusting of old and new arches over synclinal troughs. - - - - fold-curves and faults formed by the twisted shearing.

virgation from them of an eastern and western series of torsion-curves, representing fold-arcs; (*b*) the injection of igneous rock along the main direction of "septal" shearing, associated with the presence of larger masses in the areas of fold-expansion; (*c*) the fact that they have continued to act as lines of crust-adjustment subsequently to the period of acute torsional upheaval. In the Alps the repeated displacement of the main chain to the north would simply indicate that the arch on the east of any transverse depression had been originally less elevated than the arch on the west of the same depression. The extent to which eastern curves have been twisted away from western curves originally belonging to the same "bundle" of virgating folds, may give us some idea of the tremendous shearing that has taken place, and the great compression that the Alpine regions have sustained from east and west in virtue of this oblique, sigmoidal movement of opposite arches over intervening synclines (Fig. 3).

The law which I deduced from my observations at Sella was that the southwardly-convex torsion curves are marked by over-

thrust of the folds towards the south, the northwardly-convex curves by overthrust of the folds towards the north. This law agrees with the movements which Prof. Suess has described along the curved lines of Alpine upheaval, and finds further confirmation in the curious effects of reversal of thrust-movements which are so highly characteristic of all the great transverse Alpine arches. To cite one example, compare the great overthrusts round the south curves of the western Alps with the northwardly-directed overthrusts in the Bernese Oberland.

The drawing (Fig. 3) shows that the eastern and western fold-arcs associated with any transverse direction of faulting provide the same fundamental conditions of peripheral overthrusts with reference to definite centres which I demonstrated in Enneberg. And as the centres are comprised in the very highest transverse Alpine arches which were determined during the later epoch of Alpine upheaval, it is here that, according to torsional laws, the highest individual massives should be present.

The essential structure is the same, whether it be exemplified in the variously-shaped dolomite massives or in the variously-shaped central massives—elliptical, lenticular, or elongated, clearly or less clearly defined from one another—all may be regarded as an inevitable result of crust-torsion.

Even when considerable subsequent faulting and lateral displacement might seem to have obliterated the original relationship of opposite torsion-curves, there are long streaks or interrupted appearances of igneous injections along the main fault-line, which afford evidence of a probable original connection between eastern and western fold-arcs now fairly remote from one another.

The more or less sickle-shaped form of some Alpine curves represents a north and south fold-arc on the same side of a transverse direction of shearing. The Enneberg curve (Langs-da-Für, Campolungo, Cherz Hill) is an example on a small scale, the Banat curve round the Roumanian Plain is an example on a grand scale.

The chief line of fault there is the "Banat" line, which in its tectonic relations bears a strong resemblance to the Judicarian line. It runs north and south and separates a western area of mica schists from an eastern depressed area of Jurassic and Cretaceous strata, eruptive rocks occurring at intervals along the fault. In describing the Banat fault, Prof. Suess never doubts the Tertiary age of the folds and of the eruptive rocks associated both with the folds and with the fault. He notes the twisting character of the strike, and expressly states that the eruptive rocks "*must have been Tertiary notwithstanding the resemblance almost amounting to identity which they present with those of the Judicarian and Predazzo areas*" ("Antlitz," i. p. 623 and pp. 210-213; the italics are mine). Further, he quotes Dr. Posepny's opinion "that these eruptive masses are not masses exerting pressure, but themselves pressed. The subsidence of a neighbouring district induces such eruptions, but the eruptive masses themselves are pressed into the dykes by the pressure of the sinking masses" (*l. c.* p. 210). Similar reasoning was followed by Dr. Salomon in his paper on the Peri-Adriatic eruptive masses, wherein he advocated the theory that the Peri-Adriatic masses originated in consequence of the Peri-Adriatic subsidence, and were of the age of the subsidence.

I would be inclined to class both the Judicarian and Banat faults as phenomena of torsional eruptivity which may, upon the evidence of the sedimentary strata involved in the folds, be referred to the Mid-Tertiary epoch of Alpine upheaval.

Two great internal torsion-basins within the Alpine systems of southern Europe are the Hungarian and the west Mediterranean. The arrangement of the Carpathian mountains round the Hungarian basin presents all the characteristic features of torsion. Mountain fold-arcs have formed peripherally, and broken arches have been thrust outwards and upwards from the basin, while fold-slices produced by normal faulting have had an involute movement inward and downward. Eruptivity has been particularly active in the main septal zone between the oppositely moving portions of the fold-arcs. The Dalmatian mountains represent a series of peripheral folds whose arches have moved towards the south-west, while the eastern Alps betray the influence of this movement of folding, and also a co-ordinated movement to north-west.

The centrifugal movements round the periphery of the western part of the Mediterranean basin have caused the upfolding of the Apennines towards the north-east, and again an igneous zone runs irregularly between the area of peripheral out-thrust and inward down-throw. It is still further within the igneous zone that we must look for the buckling-up of new rock-folds, but the new folds can never be absolutely parallel with the predecessors, *since crust-torsion is going on all the time.* Hence the virgation of successively formed ranges in great mountain systems would appear to rest upon much the same principle as the virgation of fold-arcs illustrated at Gröden Pass in Enneberg (*Q.J.G.S.*, August 1899, *l.c.*, Plate I.).

While torsion-basins tend by reason of repeated buckling to narrow within themselves, the tendency of the regions outside the outermost peripheral fold-arcs is to subside towards the torsional sag. To such return involute movements we may probably attribute the present subsidence going on in the Adriatic areas, as also the tendency for lakes and plains to form on the outer skirts of torsional mountain-systems.

The Caucasus mountains afford an example of the occurrence of an internal area of down-throw in various parts of which

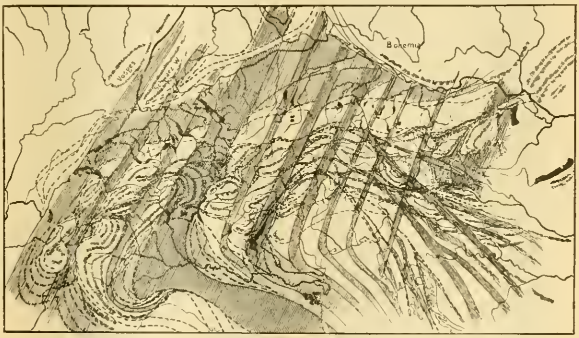

FIG. 3.—The leading oblique arches and troughs of the Tertiary upheaval of the Alps. (The troughs are shaded, the arches are between the troughs, and the chief fold-arcs of the mountain masses are indicated within the arches by shading and broken lines.)

vulcanicity has been active, and of outer areas along which overcast folds of immense size have been gradually involuted. The Alps show at the present day an advanced phase in their torsional history. Earlier outer folds have been broken down owing to dynamic as well as aërial causes of denudation, and have disappeared along interrupted outer shear-zones which I would identify as those occupied by "Flysch" rocks of whatever age. These rocks represent the necessary deformation of older and less twisted folds by the process of involution during the gradual evolution of later and more twisted folds.

Such an explanation of the relation of the Flysch to the present Alps would agree with the observed fact that fragments of granitoid and metamorphic rocks contained in the Flysch show less metamorphic change than those in the central massives of the Alps, since it would relate the Flysch to lost earlier folds which had undergone a smaller degree of torsion than the succeeding folds.

The widely-extended subsidence during Jurassic and the greater part of Cretaceous time in Europe seems to have been the turning-point in the history of Alpine upheaval, since previously, in Alpine regions, the resultant forces had acted more strongly from north and south than from east and west, and afterwards the movements came almost transversely. Hence the long continuation of the great Mesozoic epoch of deposition and subsidence, in inducing the strong action of east and west crust-strains over a region where previously the action of north and south crust-

strains had been pre-eminent, has probably been the initiative cause of an acute epoch of crust torsion and folding along oblique and transverse lines.

The new movements affected all European areas, dovetailing new folds into the midst of, and across, old folds, and determining new centres of virgation. In the Alps new arches and troughs were formed obliquely and transversely across the older series; the first-formed basins in the new movement were themselves over-arched or blocked up as the fan-shaped mountain-massives gradually became more and more compactly pressed together, and the great torsion-basins of southern Europe became confirmed in their new shape and position acquired in accordance with the altered conditions of crust equilibrium.

As might be expected, there is frequent indication that eruptive activity in Tertiary time broke out afresh in the same areas where eruptive activity had marked the Upper Carboniferous and Permo-Triassic period of movements. But the chief groups of eruptive rock round the inner *curves* of the Alps, Apennines and Carpathians, as well as the injections along oblique directions of shearing, may be clearly identified with the Tertiary torsion movements, for the most part, with the acute Mid-Tertiary epoch of torsion. The larger masses of igneous rocks in the central massives may belong in part to the ancient Palæozoic or Permo-Carboniferous epochs of upheaval, in part to the late-Mesozoic and Tertiary epochs.

A general conclusion may be made from the above that there are serpentines, diorites, granites, felsites, basalts in Alpine folds and faults which can be identified more especially with the "evolute" phenomena of Tertiary torsional movements. And these intrusions, injections, and eruptions involved in the last acute epoch of upheaval in Southern Europe are clearly correlated with similar eruptive phenomena throughout the same period in other parts of Europe, *e.g.* Auvergne, Scotland, Iceland.

MARIA M. OGILVIE.

## THE MOTION OF A PERFECT LIQUID.[1]

IF we look across the surface of a river, we cannot fail to observe the difference of the movement at various points. Near one bank the velocity may be much less than near the other, and generally, though not always, it is greater in the middle than near either bank. If we could look beneath the surface and see what was going on there, we should find that the velocity was not so great near the bottom as at the top, and was scarcely the same at any two points of the depth. The more we study the matter, the more complex the motion appears to be; small floating bodies are not only carried down at different speeds and across each other's paths, but are whirled round and round in small whirlpools, sometimes even disappearing for a time beneath the surface. By watching floating bodies we can sometimes realise these complex movements, but they may take place without giving the slightest evidence of their existence.

You are now looking at water flowing through a channel of varying cross section, but there is very little evidence of any disturbance taking place. By admitting colour, although its effect is at once visible on the water, it does not help us much to understand the character of the flow. If, however, fine bubbles of air are admitted, we at once perceive (Fig. 1) the tumultuous conditions under which the water is moving and that there is a strong whirlpool action. This may be intensified by closing in two sides (Fig. 2), so as to imitate the action of a sluice gate, through the narrow opening of which the water has all to pass, the presence of air making the disturbed behaviour of the water very evident.

FIG. 1

FIG. 2.

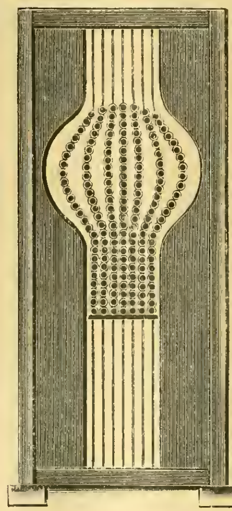

FIG. 3.

Now you will readily admit that it is hopeless to begin to study the flow of the water under such conditions, and we naturally ask, are there not cases in which the action is more simple? Such would be the case if the water flowed very slowly in a perfectly smooth and parallel river bed, when the particles would follow one another in lines called "stream-lines," and the flow would be like the march of a disciplined army, instead of like the movement of a disorderly crowd, in which free fights taking place at various points may be supposed to resemble the local disturbances of whirlpools or vortices.

The model (Fig. 3) represents on a large scale a section of the channel already shown, in which groups of particles of the water are indicated by round balls, lines in the direction of flow of these groups (which for convenience we may call particles) being coloured alternately. When I move these so that the lines are maintained, we imitate "stream-line" motion, and when, at any given point of the pipe, the succeeding particles always move at exactly the same velocity, we have what is understood as "steady motion."

[1] A discourse delivered at the Royal Institution on Friday, February 10, by Prof. H. S. Hele-Shaw.

As long as all the particles move in the straight portion of the channel, their behaviour is easy enough to understand. But as the channel widens out, it is clear that this model does not give us the proper distribution. In the model the wider portions are not filled up, as they would be with the natural fluid; for it must be clearly understood that the stream-lines do not flow on as the balls along these wires, passing through a mass of dead water, but redistribute themselves so that every particle of water takes part in the flow. Perhaps you may think that if these wires were removed, and the wooden balls allowed to find their own positions, they would group themselves as with an actual liquid. This is not the case; and, for reasons that you will see presently, no model of this kind would give us the real conditions of actual flow. By means of a model, however, we may be able to understand why it is so absolutely essential we should realise the correct nature of the grouping which occurs.

First look at the two diagrams (Figs. 4 and 5), which you will see represent channels of similar form to the experimental one. The same number of particles enter and leave in each under apparently the same conditions, so that the idea may naturally arise in your minds, that if the particles ultimately flow with the same speed whatever their grouping in the larger portion of the channel, it cannot much matter in what particular kind of formation they actually pass through that wider portion. To understand that is really very important. Let us consider a

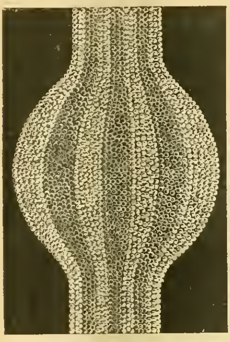

FIG. 4.

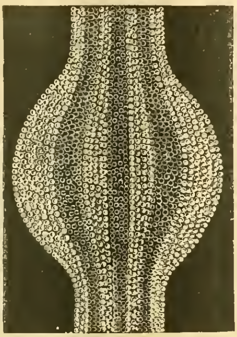

FIG. 5.

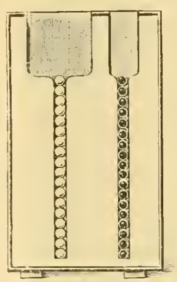

FIG. 6.

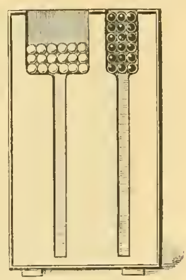

FIG. 7.

model (Fig. 6) specially made for the purpose. You will see that we have two lines of particles which we may consider stream-lines, those on the left coloured white, and those on the right coloured red. The first and last are now exactly 18 inches apart, there being eighteen balls of 1 inch diameter in the row. If I move the red ones upward, I cause them to enter a wider portion of the channel, where they will have to arrange themselves so as to be three abreast (Fig. 7). It is quite clear to you, that as I do this their speed in the wider portion of the channel is only one-third of that in the narrow portion, as you will see from the relative positions of the marked particles. Now, directly the first particle entered the wider channel, it commenced to move at a reduced speed, with the result that the particles immediately behind it must have run up against it, exactly in the same way that you have often heard the trucks in a goods train run in succession upon the ones in front, when the speed of the engine is reduced; and you will doubtless have noticed that it was not necessary for the engine actually to stop in order that this might take place. Moreover, the force of the impact depended largely upon the suddenness with which the speed of those in front was reduced. Applying this illustration to the model, you will see that the impact of these particles in the wider portion would necessarily involve a greater pressure in that part. Turning next to the white balls, I imitate, by means of the left-hand portion, the flow which will occur in a channel six times as large as the original one, and you now see (Fig. 7) that as the particles have placed themselves six abreast, and the first and last row are 3 inches apart instead of 18 inches, the speed in the wider portion of the channel must have been one-sixth of that in the narrow portion. Evidently, therefore, the velocity of the particles has been reduced more rapidly than in the previous case, and the pressure must consequently be correspondingly greater.

We may now take it as perfectly clear and evident, that the pressure is greater in the wider portion and less in the narrower portion of the channel. Turning now to the two diagrams, we see that the pressure is in each case greater in every row of particles as in the wider portions of the channel, but that instead of being suddenly increased, as in the model, it is gradually increased. The width of the coloured bands, that is, rows of particles, or width apart of stream-lines, is a measure of the increased pressure. Thus you will now regard the width of the bands, or what is the same thing, the distance apart of the stream-lines, as a direct indication of pressure, and the narrowness or closeness of the stream-lines as a direct indication of velocity.

Next notice the great difference between the two diagrams. In one diagram (Fig. 4) the change of width is uniform across the entire section. In diagram (Fig. 5), however, this is not the case. In the narrowest portion of the channel in each diagram there are seven colour bands of little balls each containing three abreast, but we find that in one diagram (Fig. 4) they are equally spaced in the wider part six abreast throughout. In the other diagram (Fig. 5) the outer row is spaced eight abreast, the second row rather more than six, and the inner rows rather more than four abreast, and the middle row less than four abreast, making in all forty-two in a row, as in the previous case. One diagram (Fig. 5) therefore will represent an entirely different condition to the state represented by the other diagram (Fig. 4), the pressure in the wide part of the latter varying from a maximum at the outside to a minimum in the middle, while the corresponding velocity is greatest in the middle and least at the outside or borders.

Now, when we know the pressure at every point of a liquid, and also the direction in which the particles are moving, together with their velocity at every point, we really know all about its motion, and you will see how important the question of grouping is, and that, in fact, it really constitutes the whole point of my lecture to-night. How then shall we ascertain which of the two groupings (Fig. 4 or 5) is correct, or whether possibly some grouping totally different from either does not represent the real conditions of flow?

Now, the model does not help us very far, because there seems to be no means of making the grouping follow any regular law which might agree with fluid motion. In whatever way we improve such a model, we can scarcely hope to imitate by merely mechanical means the motion of an actual liquid, for reasons which I will now try to explain.

In the first place, apart from the particles having no distinguishing characteristics, either when the liquid is opaque or transparent, they are so small and their number is so great as to be almost beyond our powers of comprehension. Let me try, by means of a simple illustration, to give some idea of their number, as arrived at by perfectly well recognised methods of physical computation. Lord Kelvin has used the illustration that, supposing a drop of water were magnified to the size of the

earth, the ultimate particles would appear to us between the size of cricket-balls and foot-balls. I venture to put the same fact in another way, that may perhaps strike you more forcibly. This tumbler contains half a pint of water. I now close the top. Suppose that, by means of a fine hole, I allow one and a half billion particles to flow out per second—that is to say, an exodus equal to about one thousand times the population of the world in each second,—the time required to empty the glass would be *between* (for of course we can only give certain limits) seven million and forty-seven million years.

In the next place, we have the particles interfering with each other's movements by what we call "viscosity."

Of course, the general idea of what is meant by a "viscous" fluid is familiar to everybody, as that quality which treacle and tar possess in a marked degree, glycerine to a less extent, water to a less extent than glycerine, and alcohol and spirits least of all. In liquids, the property of viscosity resembles a certain positive "stickiness" of the particles to themselves and to other bodies; and would be well represented in our model by coating over the various balls with some viscous material, or by the clinging together, which might take place by the individuals of a crowd, as contrasted with the absence of this in the case of no viscosity as represented by the evolutions of a body of soldiers. It may be accounted for, to a certain extent, by supposing the particles to possess an irregular shape, or to constantly move across each other's paths, causing groups of particles to be whirled round together.

Whatever the real nature of viscosity is, it results in producing in water the eddying motion which would be perfectly impossible if viscosity were absent, and which makes the problem of the motion of an imperfect liquid so difficult and perplexing.

Now, all scientific advance in discovering the laws of nature has been made by first simplifying the problem and reducing it to certain ideal conditions, and this is what mathematicians have done in studying the motion of a liquid.

We have already seen what almost countless millions of particles must exist in a very small space, and it does require a much greater stretch of the imagination to consider their number altogether without limit. If we then assume that a liquid has no viscosity, and that it is incompressible, and that the number of particles is infinite, we arrive at a state of things which would be represented in the case of the model or the diagram on the wall, when the little globes were perfectly smooth, perfectly round and perfectly hard, all of them in contact with each other, and with an unlimited number occupying the smallest part of one of the coloured or clear bands. This agrees with the mathematical conception of a perfect liquid, although the mathematician has in his mind the idea of something of the nature of a jelly consisting of such small particles, rather than of the separate particles themselves. The solution of the problem of the grouping of the little particles, upon which so much depends, and which may have at first seemed so simple a matter, really represents, though as yet applied to only a few simple cases, one of the most remarkable instances of the power of higher mathematics, and one of the greatest achievements of mathematical genius.

You will be as glad as I am that it is not my business to-night to explain the mathematical processes by which the behaviour of a perfect liquid has been to a certain extent investigated. You will also understand why such models as we could actually make, or any analogy with the things with which we are familiar, would not help us very much in obtaining a mental picture of the behaviour of a perfect liquid. If, for instance, we try to make use of the idea of drilled soldiers, and move the lines with that object in view, we see that instead of the ordinary methods of drill, the middle rank soon gains on the others, and enters again the parallel portion of the channel in a very different relative position to the opposite lines, although the stream-lines would all have the same actual velocity when once again in the parallel portion. Since, then, we cannot use models or any simple analogy with familiar things, or follow—at any rate this evening—the mathematical methods of dealing with the problem, what way of understanding the subject is left to us?

If we take two sheets of glass, and bring them nearly close together, leaving only a space the thickness of a thin card or piece of paper, and then by suitable means cause liquid to flow under pressure between them, the very property of viscosity, which, as before noted, is the cause of the eddying motion in large bodies of water, in the present case greatly limits the freedom of motion of the fluid between the two sheets of glass, and thus prevents, not only eddying or whirling motion, but also counteracts the effect of inertia. Every particle is then compelled by the pressure behind and around it to move onwards without whirling motion, following the path which corresponds exactly with the stream-lines in a perfect liquid.

If we now, by a suitable means, allow distinguishing bands of coloured liquid to take part in the general flow, we are able to imitate exactly the conditions we are seeking to understand.

[Prof. Hele-Shaw here gave demonstrations of the stream-lines in liquids flowing under the conditions of a gradually enlarging and contracting channel. He proved that the condition of flow corresponded closely with that shown in Fig. 5 and *not* with that given in Fig. 4. The method of the experiments has already been described in NATURE (vol. lviii. p. 34), though by using glycerine instead of water much more perfect results were obtained than in those then described.]

But at this stage you may reasonably inquire how it is that we are able to state, with so much certainty, that the artificial conditions of flow with a viscous liquid are really giving us the stream-line motion of a perfect one; and this brings me to the results which mathematicians have obtained.

The view now shown represents a body of circular cross-section, past which a fluid of infinite extent is moving, and the lines are plotted from mathematical investigation and represents the flow of particles. This particular case gives us the means

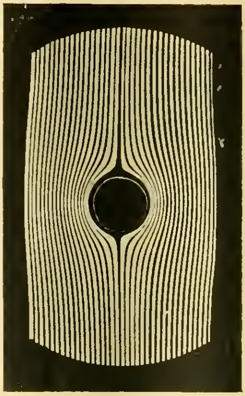

FIG. 8.

of most elaborate comparison; although we cannot employ a fluid of infinite extent, we can prepare the border of the channel to correspond with any one of the particular stream-lines, and measure the exact positions of the lines inside.

By means of a second lantern, the real flow of a viscous liquid for this case is shown upon the second screen, and you will see that it agrees with the calculated flow round a similar obstacle of a perfect liquid. The diagram shown on the wall is the actual figure employed for comparison, and upon which the experimental case was projected. By this means, it was proved that the two were in absolute agreement. If we start the impulses, as before, in a row, we at once see how the middle particles lag behind the outer ones, as indicated by the width of the bands, showing that it is not necessarily the side stream-lines that move more slowly. It may be more interesting to you to see, in addition to the foregoing case in which for convenience, and as quite sufficient for measurement only, a semi-cylinder was employed—the case of a complete cylinder (Fig. 8). In this case two different colours are used in alternate bands, and these bands are sent in, not steadily, but impulsively, in order to illustrate what I have just pointed out. You will see how the greater width of the colour bands before and behind the cylinder indicates an increase of pressure in those regions. This in a ship-shape form accounts for the standing bow and stern

waves, whereas the narrowing of the bands at the sides indicates an increase of velocity and reduction of pressure, and accounts for the depression of water level, with which you are doubtless familiar, at the corresponding part of a ship.

I will now take a more striking case. If, instead of a circular body, we had a flat plate, the turbulent nature of the flow is evidently very great, as you will see from the view (Fig. 9), which is a photograph of the actual flow under these conditions, made visible by very fine air bubbles, and showing water at rest in the clear space behind the obstacle.

We can, however, take steps to reduce this turbulence, and you now see on the second screen the flow by means of apparatus which time does not permit me to describe, but which gives a slow and steady motion that it would be impossible to improve upon in actual conditions of practice, or even, I am inclined to think, by any experimental method. Instead of using air to

Fig. 9.

make this flow clear, we now allow colour to stream behind the plate, and you will see that the water still refuses to flow round to the back, and spreads on either side. We have so slow a velocity as not to induce vortex motion, but the inertia of the particles which strike the flat plate causes them to be deflected to either side, exactly as tennis-balls in striking against a wall obliquely. The sheet of water is so thick, that is to say, the parallel glass plates are so far apart, that they do not enable the viscosity of the water to act as a sufficient drag to prevent this taking place.

Mathematicians, however, predicted with absolute certainty that with stream-line motion, the water should flow round and meet at the back, a state of things that, however slow we make the motion in the present case, does not occur owing to the effect of inertia. They have drawn with equal confidence the lines along which this should take place. We could either effect this result with the experiment you have just seen, by using a much more viscous liquid, such as treacle, or, what comes to the same thing, bringing the two sheets of glass nearly close together; and the flow which you are now witnessing (Fig. 10) shows the result of doing this. The colour bands in front of the plate no longer mix at all with the general body of flow, or are unsteady, as was the case in the last experiment, but flow round the plate, and flow so steadily, that unless we jerk the flow of the colour bands, it is impossible to tell in which direction they are actually moving. It is interesting to note that where the divided central colour band re-unites is clearly shown in the illustration.

Whilst I have been dealing with the stream-lines of a perfect liquid, your minds will doubtless have turned to the lines along which magnetic and electrical forces appear to act. We are possibly further from realising the actual nature of these forces, than from a correct conception of the real nature of a liquid. We have long agreed to abandon the old ideas of the electrical and magnetic fluids flowing along these lines, and to substitute instead the idea that these lines represent merely the directions in which the forces act. Now we can easily see that this conception is quite a reasonable one, for in the case of the model it is not necessary to have the row of balls actually moving in order that the effect may be transmitted along the different lines they occupy. If I attempt to raise the plate upon which they rest, the pressure is instantly transmitted through

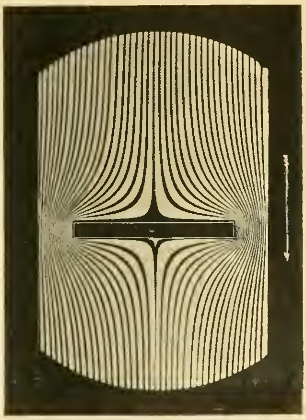

Fig. 10

the whole row to the top ball along each line, whatever curve the line may take. In the same way, you will remember that it was not necessary to have the colour bands actually in motion, for, though apparently free to move in any direction, they retain their form for a considerable time, and the path along which they would influence each other as soon as the tap is opened would be along those lines in which the liquid was flowing before it was brought to rest. Hence it is possible, with some suitable means, to cause a viscous liquid to reproduce exactly the lines of magnetic and electrical induction. In the case of magnetism and electricity, it is of course possible, by means of a small magnetic needle or a galvanometer, by exploring the whole surface through which magnetic induction or electrical flow is acting, to plot the lines of force for innumerable cases, where we can work in air or on the surface of the solid conductor.

But in this building it seems natural to take as an example the case first used by the great man to whom the conception of lines of magnetic force is due, for the first reference I have been able to find to such lines is in one of Faraday's earliest papers on the indication of electric currents ("Experimental Researches in Electricity," vol. i. p. 32), in which he says, "By magnetic curves I mean the lines of magnetic forces, however modified by the juxtaposition of poles, which would be depicted by iron

filings, or those to which a very small magnetic needle would form a tangent."

You are all familiar with the way in which iron filings set themselves when shaken over the north and south poles of a magnet. The magnetic lines are then nearly, but not quite, circular curves between the two poles. Now, the mathematics of the subject tells us that if the poles could be regarded as points, the lines of force between them would be perfect circles.

You are now looking at the colour bands, the edges—or indeed any portion—of which represent lines obtained by admitting coloured liquid from a series of small holes round a central small orifice, which admits clear liquid, and allows them to escape through another small orifice (called respectively in hydromechanics a *source* and *sink*), and I leave it to you to judge how far these curves deviate from the ideal form.

My assistant is now allowing the colour to flow, first steadily, and then in a series of impulses, and the latter gives us the conception of waves or impulses of magnetic force, though of course the magnetic transmission force would be instantaneous. Regarded as a liquid, it is here again clear how absolutely the truth of our views concerning the slower movement in the wider portion is verified by this experiment.

A last experiment shows the streams admitted, not from a source, but from a row of orifices in what corresponds to the slowest moving portion of the flow. The result is that the colour bands are much narrower, and although the circular forms of the curves are, as in the previous experiment, preserved, the lines are so fine at the point of exit, which, as before, corresponds to the South Pole, as to really approximate to ideal stream-lines.

The same method enables us to trace the lines of force through solid conductors, for, as long as we confine ourselves to two dimensions of space we may have *flat* conductors of any shape whatever. But it does something more, for by making the film rather deeper in some places than others, more particles arrange themselves there, and the lines of flow will naturally tend in the direction of the deeper portion. This will give the stream-lines identically the same shape as the magnetic or electrical curves which encounter in their paths a body of less resistance, for instance, a para-magnetic body.

If, on the other hand, at these points the film is made rather thinner, less particles will be able to dispose of themselves in the shallow portion of the film, and hence the lines of flow will be pushed away from this portion, giving us exactly the same forms as magnetic lines of force in a magnetic field in proximity to a diamagnetic body.

Here, again, mathematical methods have enabled lines of actual flow to be predicted, and you may compare the actual flow for the case of a cylindrical para-magnetic body, which was worked out some years ago.

You will doubtless not be inclined to question the practical value of stream-lines in the subject which we have just been considering, because, unlike the flow of an actual liquid, magnetic lines of force can never be themselves seen, and because there is no doubt as to the correspondence of the directions to the lines of a perfect liquid. It was the conception of these lines in the mind of Faraday, and more particularly their being cut by a moving wire, that enabled him to realise the nature of the subject more clearly than any other man at the time, and to do much towards the rapid development of electrical science and its practical applications.

When we come to consider the relation of the study of the motion of a perfect liquid with hydromechanics and naval architecture, it must be admitted that the matter is a difficult one. Probably one of the most perplexing things in engineering science is the absence of all apparent connection between higher treatises on hydrodynamics and the vast array of works on practical hydraulics. The natural connection between the treatises of mathematicians and experimental researches of engineers would appear to be obvious, but very little, if any, such connection exists in reality, and while at every step electrical applications owe much to the theories which are common to electricity and hydromechanics, we look in vain for such applications in connection with the actual flow of water.

Now the reason for this appears to be the immense difference between the flow of an actual liquid and that of a perfect one owing to the property of viscosity. A comparison of the various experiments which you have seen to some extent indicates this.

In the first place, let us consider for a moment some of the things which would happen if water were a perfect liquid. In such a case, a ship would experience a very different amount of resistance, because, although waves would be raised, owing to the reasons which we have already seen, the chief causes of resistance, viz. skin friction and eddying motion, would be entirely absent, and of course a submarine boat at a certain depth would experience no resistance at all, since the pressures fore and aft would be equal. On the other hand, there would be no waves raised by the action of the wind, and there would be no tidal flow, but to make up for this rivers would flow with incredible velocity, since there would be no retarding forces owing to the friction of the banks. But the rivers themselves would soon cease to flow because there would be no rainfall such as exists at present, since it is due to viscosity that the rain is distributed, instead of falling upon the earth in a solid mass when condensed. In a word, it may be said that the absence of viscosity in water would result in changes which it is impossible to realise.

We may now briefly try to consider the difference between practical hydraulics and the mathematical treatment of a perfect liquid. The earliest attempts to investigate in a scientific way the flow of water appears to have been made by a Roman engineer about 1800 years ago, an effort being made to find the law for the flow of water from an orifice. For more than 1500 years, however, even the simple principle of flow according to which the velocity of efflux varies as the square of the head, or what is the same thing, the height of surface above the orifice varies as the square of the velocity, remained unknown. Torricelli, who discovered this, did so as the result of observing that a jet of water rose nearly to the height of the surface of the body of water from which it issued, and concluded therefore that it obeyed the then recently discovered law of all falling bodies.

Though it was obvious that this law did not exactly hold, it was a long time before it was realised that it was the friction or viscosity of liquids that caused so marked a deviation from the simple theory. Since then problems in practical hydraulics, whether in connection with the flow in rivers or pipes, or the resistance of ships, have largely consisted in the determination of the amount of deviation from the foregoing simple law.

About one hundred years ago it was discovered that the resistance of friction varies nearly in accordance with the simple law of Torricelli, and also—although for a totally different reason—the resistances due to a sudden contraction or enlargement of cross-section of channel or to any sudden obstructions appear to follow nearly the same law. Now it is extremely convenient for reasons which will be understood by students of hydraulics to treat all kinds of resistance as following the same law, viz. square of velocity which the variation of head or height of surface has shown to do. But this is far from being exact, and an enormous amount of labour has consequently been expended in finding for all conceivable conditions in actual work tables of coefficients or empirical expressions which are required for calculations of various practical questions. Such data are continually being accumulated in connection with the flow of water in rivers and pipes for hydraulic motors and naval architecture. This is the practical side of the question.

On the other hand, eminent mathematicians, since the days of Newton and the discovery of the method of the calculus, have been pursuing the investigation of the behaviour of a perfect liquid. The mathematical methods, which I have already alluded to as being so wonderful, have, however, scarcely been brought to bear with any apparent result upon the behaviour of a viscous fluid. Indeed, the mathematician has not been really able to adopt the method of the practical investigator, and deal with useful forms of bodies such as those of actual ships, or of liquid moving through ordinary channels of varying section, even for the case of a perfect liquid, but he has had to take those cases, and they are very few indeed, that he has been able to discover which fit in with his mathematical powers of treatment.

This brief summary may possibly serve to indicate the nature of the difficulties which I have pointed out, and will show you the vast field there yet lies open for research in connection with the subject of hydromechanics, and the great reception which awaits the discovery of a theoretical method of completely dealing with viscous liquids, instead of having recourse as at present principally to empirical formula based on the simple law already alluded to.

We may, however, console ourselves with the thought, that in the application of the laws of motion themselves to *any* terrestrial matters, the friction of bodies must always be taken into account, and renders it necessary, that we should commence by studying the ideal conditions. In this as in other matters, the naval architect and engineer must always endeavour as far as possible to base their considerations and work upon the secure foundation of scientific knowledge, making allowances for disturbing causes, which then cease to be the source of perplexity and confusion. From this point of view, the study of the behaviour of a perfect liquid, even when no such form of matter appears to exist, has an interest for the practical man in spite of the deviation of actual liquids from such ideal conditions. If the truth must be told, it is such a deviation from the simple and ideal conditions that really constitute the work of a professional man, and it is only practical experience which, based upon sound technical knowledge, enables 50,000 tons of steel to be made to span the Firth of Forth, Niagara to be harnessed to do the work of 100,000 horses, or an *Oceanic* to be slid into the sea with as little misgiving as the launch of a fishing-boat.

I have, I am afraid, brought you only to the threshold of a vast subject, and in doing so have possibly employed reasoning of too elementary a kind. After all, I may plead that I have followed the dictum of Faraday, who said, "If assumptions must be made, it is better to assume as little as possible." If I have assumed too little knowledge on your part, it is because of the difficulties I have found in the subject myself. If I have left more obscure than I have been able to make clear, it is consoling to think how many centuries were required to discover even what is known at the present time, and we may well be forgiven if we cannot grasp at once results which represent the life-work of some of the greatest men.

## A PROBLEM IN AMERICAN ANTHROPOLOGY.[1]

WHILE engaged in writing the address that I am to read to you this evening, the sad news reached me of the death, on July 31, of our President of five years ago, Dr. D. G. Brinton. Although not unexpected, as his health had been failing since he was with us at the Boston meeting, where he took his always active part in the proceedings of Section H, and gave his wise advice in our general council, yet his death affects me deeply. I was writing on a subject we had often discussed in an earnest but friendly manner. He believed in an all-pervading psychological influence upon man's development, and claimed that American art and culture were autochthonous, and that all resemblances to other parts of the world were the results of corresponding stages in the development of man; while I claimed that there were too many root coincidences with variant branches to be fully accounted for without also admitting the contact of peoples. Feeling his influence while writing, I had hoped that he would be present to-night, for I am certain that no one would have more readily joined with me in urging a suspension of judgment, while giving free expression to opinions, until the facts have been worked over anew, and more knowledge attained.

Now that his eloquent tongue is silent and his gifted pen is still, I urge upon all who hear me to-night to read his two addresses before this Association—one as Vice-President of the Anthropological Section in 1887, published in our thirty-sixth volume of *Proceedings*, the other as retiring President in 1895, published in our forty-fourth volume. In these addresses he had in his usual forcible and comprehensive manner presented his views of American anthropological research and of the aims of anthropology.

Dr. Brinton was a man of great mental power and erudition. He was an extensive reader in many languages, and his retentive memory enabled him to quote readily from the works of others. He was a prolific writer, and an able critic of anthropological literature the world over. Doing little as a field archæologist himself, he kept informed of what was done by others through extensive travels and visits to museums. By his death American anthropology has suffered a serious loss, and a great scholar and earnest worker has been taken from our Association.

[1] Address delivered before the American Association for the Advancement of Science, at Columbus, Ohio, on August 21, by Prof. Frederic Ward Putnam, the retiring President of the Association.

In the year 1857 this Association met for the first time beyond the borders of the United States, thus establishing its claim to the name American in the broadest sense. Already a member of a year's standing, it was with feelings of youthful pride that I recorded my name and entered the meeting in the hospitable city of Montreal, and it was on this occasion that my mind was awakened to new interests which in after years led me from the study of animals to that of man.

On Sunday, August 16, while strolling along the side of Mount Royal, I noticed the point of a bivalve shell protruding from roots of grass. Wondering why such a shell should be there, and reaching to pick it up, I noticed on detaching the grass roots about it that there were many other whole and broken valves in close proximity—too many, I thought, and too near together, to have been brought by birds, and too far away from water to be the remnants of a musk-rat's dinner. Scratching away the grass and poking among the shells, I found a few bones of birds and fishes and small fragments of Indian pottery. Then it dawned upon me that there had been an Indian home in ancient times, and that these odds and ends were the refuse of the people—my first shell-heap or kitchen-midden, as I was to learn later. At the time this was to me simply the evidence of Indian occupation of the place in former times, as convincing as was the palisaded town of old Hochelaga to Cartier when he stood upon this same mountain side more than three centuries before.

At that meeting of the Association several papers were read, which, had there been a section of anthropology, would have led to discussions similar to those that have occurred during our recent meetings. Forty-two years later we are still disputing the evidence, furnished by craniology, by social institutions and by language, in relation to the unity or diversity of the existing American tribes and their predecessors on this continent.

Those were the days when the theory of the unity of all American peoples, except the Eskimo, as set forth by Morton in his "Crania Americana" (1839), was discussed by naturalists. The volumes by Nott and Gliddon, "Types of Mankind" (1854) and "Indigenous Races of the Earth" (1857), which contains Meigs' learned and instructive dissertation, "The Cranial Characteristics of the Races of Men," were the works that stirred equally the minds of naturalists and of theologians regarding the unity or diversity of man—a question that could not then be discussed with the equanimity with which it is now approached. The storm caused by Darwin's "Origin of Species" had not yet come to wash away old prejudices and clear the air for the calm discussion of theories and facts now permitted to all earnest investigators. Well do I remember, when, during those stormy years, a most worthy Bishop made a fervent appeal to his people to refrain from attending a meeting of the Association then being held in his city, on account of what he claimed to be the atheistic teachings of science. Yet ten years later this same venerable Bishop stood before us, in that very city, and invoked God's blessing upon the noble work of the searchers for truth.

At the meeting of 1857 one of our early presidents, the honoured Dana, read his paper entitled "Thoughts on Species," in which he described a species as "a specific amount or condition of concentrated force defined in the act or law of creation," and, applying this principle, determined the unity of man in the following words:—

"We have therefore reason to believe, from man's fertile intermixture, that he is one in species; and that all organic species are divine appointments which cannot be obliterated unless by annihilating the individuals representing the species."

Another paper was by Daniel Wilson, recently from Scotland, where six years before he had coined that most useful word "prehistoric," using the term in the title of his volume, "Prehistoric Annals of Scotland." In his paper Prof. (afterwards Sir Daniel Wilson controverted the statement of Morton that there was a single form of skull for all American peoples, north and south, always excepting the Eskimo. After referring to the views of Agassiz, as set forth in the volumes of Nott and Gliddon, he said, "Since the idea of the homogeneous physical characteristics of the whole aboriginal population of America, extending from Terra del Fuego to the Arctic circle, was first propounded by Dr. Morton, it has been accepted without question, and has more recently been made the basis of many widely comprehensive deductions. Philology and archæology have also been called in to sustain this doctrine of a special unity of the American race; and to prove that, notwithstanding

some partial deviations from the prevailing standard, the American Indian is essentially separate and peculiar; *a race distinct from all others*. The stronghold, however, of the argument for the essential oneness of the whole tribes and nations of the American continents is the supposed uniformity of physiological, and especially of physiognomical and cranial characteristics; an ethnical postulate which has not yet been called in question."

After a detailed discussion of a number of Indian crania from Canada and a comparison with those from other parts of America, as described by Morton, he makes the following statements:—"But, making full allowance for such external influences, it seems to me, after thus reviewing the evidence on which the assumed unity of the American race is formed, little less extravagant to affirm of Europe than of America, that the crania everywhere and at all periods have conformed, or even approximated, to one type."

"As an hypothesis, based on evidence accumulated in the "Crania Americana," the supposed homogeneity of the whole American aborigines was perhaps a justifiable one. But the evidence was totally insufficient for any such absolute and dogmatic induction as it has been made the basis of. With the exception of the ancient Peruvians, the comprehensive generalisations relative to the southern American continent strangely contrast with the narrow basis of the premises. With a greater amount of evidence in reference to the northern continent, the conclusions still go far beyond anything established by absolute proof; and the subsequent labours of Morton himself, and still more of some of his successors, seem to have been conducted on the principle of applying practically, and in all possible bearings, an established and indisputable scientific truth, instead of testing by further evidence a novel and ingenious hypothesis."

At the close of this instructive paper are the following words: "If these conclusions, deduced from an examination of Canadian crania, are borne out by the premises and confirmed by further investigation, this much at least may be affirmed: that a marked difference distinguishes the northern tribes, now or formerly occupying the Canadian area, in their cranial conformation, from that which pertains to the aborigines of Central America and the southern valley of the Mississippi; and in so far as the northern differ from the southern tribes, they approximate more or less, in the points of divergence, to the characteristics of the Esquimaux: that intermediate ethnic link between the Old and the New World, acknowledged by nearly all recent ethnologists to be physically a Mongol and Asiatic, if philologically an American."

The third paper of the meeting to which I shall refer was by another of our former presidents, the then well-known student of Indian institutions and the author of the "League of the Iroquois" (1851). In this paper, on "The Laws of Descent of the Iroquois," Morgan discusses the league as made up of five nations, each of which was subdivided into tribes, and he explains the law of marriage among the tribes, the family relationship and the descent in the female line, as essential to the maintenance of the whole system. He then says:—

"Now the institutions of all the aboriginal races of this continent have a family cast. They bear internal evidence of a common paternity, and point to a common origin, but remote, both as to time and place. That they all sprang from a common mind, and in their progressive development have still retained the impress of original elements, is abundantly verified. The Aztecs were thoroughly and essentially Indian. We have glimpses here and there at original institutions which suggest at once, by their similarity, kindred ones among the Iroquois and other Indian races of the present day. Their intellectual characteristics, and the predominant features of their social condition, are such as to leave no doubt upon this question; and we believe the results of modern research, upon this point, concur with this conclusion. Differences existed, it is true, but they were not radical. The Aztec civilisation simply exhibited a more advanced development of those primary ideas of civil and social life, which were common to the whole Indian family, and not their overthrow by the substitution of antagonistic institutions."

After calling attention to the fact that a similar condition exists among certain peoples of the Pacific Islands, he writes:—"Whether this code of descent came out of Asia or originated upon this continent is one of the questions incapable of proof; and it must rest, for its solution, upon the weight of evidence, or upon probable induction. Its existence among American races, whose languages are radically different, and without any traditional knowledge among them of its origin, indicates a very ancient introduction, and would seem to point to Asia as the birth-place of the system."

It would be interesting to follow the succeeding meetings of the Association, and note the recurring presentation of views which the quotations I have given show to have been most seriously discussed over a generation ago. An historical review of the literature of American anthropology during the present century would also be interesting in this connection. It is probable, however, that a review of this literature for the first half of the century would reveal the fact that the writers, with here and there a notable exception, were inclined to theorise upon insufficient data, and devoted little time to the accumulation of trustworthy facts. The presentation and discussion of carefully observed facts can almost be said to have begun with the second half of the century, and this is the only part of the subject that now commands serious attention.

A reference to the very latest *résumé* of this subject as presented in the "History of the New World called America," by Edward John Payne (vol. ii., Oxford, 1899), is instructive here. In this volume Mr. Payne admits the great antiquity and unity of the American tribes, which he considers came from Asia in pre-Glacial and Glacial times, when the north-western corner of America was connected with Asia, and when man "as yet was distinguished from the inferior animals only by some painful and strenuous form of articulate speech and the possession of rude stone weapons and implements, and a knowledge of the art of fire-kindling. Such, it may be supposed, were the conditions under which man inhabited both the old and the new world in the paleo-ethnic age. . . . Even when a geological change had separated them (the continents), some intercourse by sea was perhaps maintained—an intercourse which became less and less, until the American branch of humanity became practically an isolated race as America itself had become an isolated continent" (Preface).

Mr. Payne discusses the growth of the languages of America, the various social institutions and arts, and the migrations of these early savages over the continent, north and south, during the many centuries following, as one group after another grew in culture. He considers all culture of the people autochthonous. In writing upon the physical characters of the people, he says, "It may however be suggested that, as in the Old World, the earlier and the smaller tribes tend to dolichocephaly, while the better developed ones are rather brachycephalous, a conclusion indicating that the varying proportions of the skull should be taken less as original evidence of race than as evidence of physical improvement."

This volume by Mr. Payne is replete with similar statements of facts and theories, and shows how difficult it is for us to understand the complications of the subject before us. It cannot be denied that, taking into consideration the number of authors who have written on this subject, Mr. Payne is well supported in his theory of the autochthonous origin of all American languages, institutions and arts; but the question arises, Has not the old theory of Morton, the industrious and painstaking pioneer of American craniology, been the underlying cause of this, and have not the facts been misinterpreted? At the time of Morton, the accepted belief in the unity and universal brotherhood of man was about to be assailed, and it seems, as we now look back upon those times of exciting and passionate discussions, that Morton may have been influenced by the new theory that was so soon to become prominent, namely, that there were several distinct creations of species of the genus *Homo*, and that each continent or great area had its own distinct fauna and flora. Certainly Morton ventured to make a specific statement from a collection of crania which would now be regarded as too limited to furnish true results.

The anthropologist of to-day would hardly venture to do more than to make the most general statement of the characters of any race or people from the examination of a single skull, although after the study of a large number of skulls from a single tribe or special locality he would probably be able to select one that was distinctly characteristic of the special tribe or group to which it pertained.

Relatively long and narrow heads and broad and short heads occur almost everywhere in greater or less proportion. In determining the physical characters of a people, so far as this can be done from a study of crania, the index of the height of

the skull is quite as important as that of its breadth. These indices simply give us the ready means of expressing by figures the relative height and breadth of one skull in comparison with another—a small part of what the zoologist would consider in describing, for instance, the skulls of different species of the genus *Canis*. So in our craniological studies we should determine the relative position, shape and proportions of the different elements of the skull. In fact we should approach the study of human crania with the methods of the zoologist, and should use tables of figures only so far as such tables give us the means of making exact comparisons. Here again are the anthropologists at a disadvantage, inasmuch as it is only very recently that we are approaching a standard of uniformity in these expressions. It is now more than ever essential that anthropologists should agree upon a method of expressing certain observed facts in somatology, so that the conscientious labours of an investigator, who has a special opportunity for working upon one group of man, may be made available for comparison by investigators of other groups.

Probably the old method, still largely in vogue, of stating averages is responsible for many wrong deductions. If we take one hundred or more skulls of any people, we shall find that the two extremes of the series differ to a considerable extent from those which naturally fall into the centre of the series. These extremes in the hands of a zoologist would be considered the sub-varieties of the central group or variety. So in anthropology, we should take the central group of the series as furnishing the true characters of the particular variety or group of man under consideration, and should regard the extremes as those which have been modified by various causes. It may be said that this central group is defined by stating the mean of all the characters; but this is hardly the case, for by giving the mean of all we include such extraneous characters as may have been derived by admixture or from abnormal conditions.

The many differing characteristics exhibited in a large collection of crania, brought together from various portions of America, north and south, it seems to me, are reducible to several great groups which may be generally classed as the Eskimo type, the northern and central or so-called Indian type, the north-western brachycephalic type, the south-western dolichocephalic type, the Toltecan brachycephalic type, and the Antillean type, with probably the ancient Brazilian, the Fuegian and the pre-Inca types of South America. Each of these types is found in its purity in a certain limited region, while in other regions it is more or less modified by admixture. Thus the Toltecan or ancient Mexican type (which, united with the Peruvian, was separated as the Toltecan family even by Morton) occurs, more or less modified by admixture, in the ancient and modern pueblos and in the ancient earth-works of our central and southern valleys. In Peru, more in modern than in ancient times, there is an admixture of two principal types. At the north of the continent we again find certain traits that possibly indicate a mixture of the Eskimo with the early coast peoples both on the Pacific and on the Atlantic sides of the continent. The North-central Indian type seems to have extended across the Continent and to have branched in all directions, while a similar but not so extensive branching, north-east and south, seems to have been the course of the Toltecan type.

This is not theorising upon the same facts from which Morton drew the conclusion that all these types were really one and the same. Since Morton's time we have had large collections of crania for study, and the crania have been correlated with other parts of the skeleton and with the arts and institutions of the various peoples.

Although these relations have been differently interpreted by many anthropologists who have treated the subject, yet to me they seem to indicate that the American continent has been peopled at different times and from various sources; that the great lapse of time since the different immigrants reached the continent has in many places brought about an admixture of the several stocks and modified to a greater or less extent the arts and customs of all, while natural environment has had a great influence upon the ethnic development of each group. Furthermore, contact of one group with another has done much to unify certain customs, while "survivals" have played an active part in the adoption and perpetuation of arts and customs not native to the people by whom they are preserved.

The Inca civilisation, a forcible one coming from the north, encroached upon that of the earlier people of the vicinity of Lake Titicaca, whose arts and customs were to a considerable extent adopted by the invaders. It is of interest here to note the resemblance of the older Andean art with that of the early Mediterranean, to which it seemingly has a closer resemblance than to any art on the American continent. Can it be that we have here an æsthetic survival among this early people, and could they have come across the Atlantic from that Eurafric region which has been the birthplace of many nations? Or is this simply one of those psychical coincidences, as some writers would have us believe? The customs and beliefs of the Incas point to a northern origin, and have so many resemblances to those of the ancient Mexicans, as hardly to admit of a doubt that in early times there was a close relation between these two widely separated centres of ancient American culture. But how did that pre-Inca people reach the Lake region? Is it not probable that some phase of this ancient culture may have reached the Andes from northern Africa? Let us consider this question in relation to the islands of the Atlantic. The Canary Islands, as well as the West Indies, had long been peopled when first known to history; the Caribs were on the northern coast of South America as well as on the islands; and, in the time of Columbus, native trading boats came from Yucatan to Cuba. We thus have evidence of the early navigation of both sides of the Atlantic, and certainly the ocean between could easily have been crossed.

One of the most interesting as well as most puzzling of the many phases of American archæology is the remarkable development of the art of the brachycephalic peoples, extending from northern Mexico, north-eastward to the Mississippi and Ohio valleys, then disappearing gradually as we approach the Alleghenies and, further south, the Atlantic coast, also spreading southward from Mexico to Honduras, and changing and vanishing in South America. Unquestionably of very great antiquity, this art, developed in the neolithic period of culture, reached to the age of metals, and had already begun to decline at the time of the Spanish conquest. How this remarkable development came to exist amid its different environments, we cannot yet fully understand; but the question arises, Was it of autochthonous origin, and due to the particular period in man's development, or was it a previously existing phase modified by new environment? For the present this question should be held in abeyance. To declare that the resemblance of this art to both Asiatic and Egyptian art is simply a proof of the psychical unity of man is assuming too much, and is cutting off all further consideration of the subject.

The active field and museum archæologist or ethnologist who knows and maintains the associations of specimens as found, and who arranges them in their geographical sequence, becomes intimately in touch with man's work under different phases of existence.

Fully realising that the natural working of the human mind under similar conditions will to a certain extent give uniform results, he has before him so many instances of the transmission of arts, symbolic expressions, customs, beliefs, myths and languages, that he is forced to consider the lines of contact and migration of peoples as well as their psychical resemblances.

It must be admitted that there are important considerations, both physical and mental, that seem to prove a close affinity between the brown type of Eastern Asia and the ancient Mexicans. Admitting this affinity, the question arises, Can there have been a migration eastward across the Pacific in neolithic times, or should we look for this brown type as originating in the Eurafric region and passing on to Asia from America? This latter theory cannot be considered as a baseless suggestion when the views of several distinguished anthropologists are given the consideration due to them. On the other hand, the theory of an early migration from Asia to America may also be applied to neolithic time.

However this may have been, what interests us more at this moment, and in this part of America, is the so-called "mound-builder" of the Ohio valley. Let us first clear away the mist which has so long prevented an understanding of this subject by discarding the term "mound-builder." Many peoples in America as well as on other continents have built mounds over their dead, or to mark important sites and great events. It is thus evident that a term so generally applied is of no value as a scientific designation. In North America the term has been applied even to refuse piles; the kitchen-middens or shell-heaps which are so numerous along our coasts and rivers have been classed as the work of the "mound-builder." Many of these shell-heaps are

of great antiquity, and we know that they are formed of the refuse gathered on the sites of the early peoples. From the time of these very early deposits to the present such refuse piles have been made, and many of the sites were reoccupied, sometimes even by a different people. These shell-heaps therefore cannot be regarded as the work of one people. The same may be said in regard to the mounds of earth and of stone so widely distributed over the country. Many of these are of great antiquity, while others were made within the historic period and even during the first half of the present century. Some mounds cover large collections of human bones, others are monuments over the graves of noted chiefs; others are in the form of effigies of animals and of man; and, in the south, mounds were in use in early historic times as the sites of ceremonial or other important buildings. Thus it will be seen that the earth-mounds, like the shell-mounds, were made by many peoples and at various times.

There are, however, many groups of earth-works which, although usually classed as mounds, are of an entirely different order of structure and must be considered by themselves. To this class belong the great embankments, often in the form of squares, octagons, ovals and circles, and the fortifications and singular structures on hills and plateaus which are in marked contrast to the ordinary conical mounds. Such are the Newark, Liberty, Highbank and Marietta groups of earth-works, the Turner group, the Clark or Hopewell group, and many others in Ohio and in the regions generally south and west of these great central settlements; also the Cahokia Mound opposite St Louis, the Serpent Mound of Adams County, the great embankments known as Fort Ancient, which you are to visit within a few days, the truly wonderful work of stone known as Fort Hill in Highland County, and the strange and puzzling walls of stone and cinder near Foster's station.

So far as these older earth-works have been carefully investigated they have proved to be of very considerable antiquity. This is shown by the formation of a foot or more of vegetable humus upon their steep sides; by the forest growth upon them, which is often of primeval character; and by the probability that many of these works, covering hundreds of acres, were planned and built upon the river terraces before the growth of the virgin forest.

If all mounds of shell, earth or stone, fortifications on hills, or places of religious and ceremonial rites, are classed, irrespective of their structure, contents, or time of formation, as the work of one people, and that people is designated "the American Indian" or the "American Race," and considered to be the only people ever inhabiting America, North and South, we are simply repeating what was done by Morton in relation to the crania of America—not giving fair consideration to differences while over-estimating resemblances. The effort to affirm that all the various peoples of America are of one race has this very year come up anew in the proposition to provide "a name which shall be brief and expressive," and at the same time shall fasten upon us the theory of unity—notwithstanding the facts show diversity—of race.

Let us now return to the builders of the older earth-works, and consider the possibility of their having been an offshoot of the ancient Mexicans. Of the crania from the most ancient earth-works we as yet know so little that we can only say that their affinities are with the Toltecan type; but of the character of the art, and particularly the symbolism expressing the religious thought of the people, we can find the meaning only by turning to ancient Mexico. What northern or eastern Indian ever made or can understand the meaning of such sculptures or such incised designs as have been found in several of the ancient ceremonial mounds connected with the great earth-works? What Indian tribe has ever made similar carved designs on human and other bones, or such singular figures, cut out of copper and mica, as were found in the Turner and Hopewell groups? or such symbolic animal forms, elaborately carved in stone, and such perfect terra-cotta figures of men and women as were found on the sacrificial altars of the Turner group? What meaning can be given to the Cincinnati Tablet, or to the designs on copper plates and shell discs from some of the southern and western burial and ceremonial mounds? I think we shall search in vain for the meaning of these many objects in the north or east, or for much that resembles them in the burial-places of those regions. On the other hand, most of these become intelligible when we compare the designs and symbols with those of the ancient Mexican and Central American peoples. The Cincinnati Tablet, which has been under discussion for over half a century, can be interpreted and its dual serpent characters understood by comparing it with the great double image known in Mexico as the Goddess of Death and the God of War; the elaborately complicated designs on copper plates, on shell discs, on human bones, and on the wing bones of the eagle, can in many instances be interpreted by comparison with Mexican carvings and with Mexican modes of symbolic expression of sacred objects and religious ideas. The symbolic animals carved on bone or in stone, and the perfection of the terra-cotta figures, point to the same source for the origin of the art.

In connection with the art of the builders, let us consider the earth structures themselves. The great mound at Cahokia, with its several platforms, is only a reduction of its prototype at Chalula. The fortified hills have their counterparts in Mexico. The serpent effigy is the symbolic serpent of Mexico and Central America. The practice of cremation and the existence of altars for ceremonial sacrifices strongly suggest ancient Mexican rites. We must also recall that we have a connecting link in the ancient pueblos of our own south-west, and that there is some evidence that in our Southern States, in comparatively recent times, there were a few remnants of this old people. It seems to me, therefore, that we must regard the culture of the builders of the ancient earth-works as one and the same with that of ancient Mexico, although modified by environment.

Our northern and eastern tribes came in contact with this people when they pushed their way southward and westward, and many arts and customs were doubtless adopted by the invaders as shown by customs still lingering among some of our Indian tribes. It is this absorption and admixture of the peoples that has in the course of thousands of years brought all our American peoples into a certain conformity. This does not, however, prove a unity of race.

It is convenient to group the living tribes by their languages. The existence of more than a hundred and fifty different languages in America, however, does not prove a common origin, but rather a diversity of origin as well as a great antiquity of man in America.

That man was on the American continent in quaternary times, and possibly still earlier, seems to me as certain as that he was on the Old World during the same period. The Calaveras skull, that bone of contention, is not the only evidence of his early occupation of the Pacific coast. On the Atlantic side, the recent extensive explorations of the glacial and immediately following deposits at Trenton, are confirmatory of the occupation of the Delaware valley during the closing centuries of the glacial period, and possibly also of the inter-glacial time. The discoveries in Ohio, in Florida, and in various parts of Central and South America, all go to prove man's antiquity in America. Admitting the great antiquity of one or more of the early groups of man on the continent, and that he spread widely over it while in the palæolithic and early neolithic stages of culture, I cannot see any reason for doubting that there were also later accessions during neolithic times, and even when social institutions were well advanced. While these culture epochs mark certain phases in the development of a people, they cannot be considered as marking special periods of time. In America we certainly do not find that correlation with the Old World periods which we are so wont to take for granted.

We have now reached the epoch of careful and thorough exploration and of conscientious arrangement of collections in our scientific museums. It is no longer considered sacrilegious to exhibit skulls, skeletons and mummies in connection with the works of the same peoples. Museums devoted primarily to the education of the public in the æsthetic arts are clearing their cases of heterogeneous collections of ethnological and archæological objects. Museums of natural history are being arranged to show the history and distribution of animal and vegetable life and the structure of the earth itself. Anthropological museums should be similarly arranged, and, with certain gaps which every curator hopes to fill, they should show the life and history of man. To this end, the conscientious curator will avoid the expression of special theories, and will endeavour to present the true status of each tribe or group of man in the past and in the present, so far as the material at his command permits. A strictly geographical arrangement is therefore the primary principle which should govern the exhibition of anthropological collections. A special exhibit may be made in order to illustrate certain methods by which man in different regions has attained similar results, either by contact

or by natural means. Another exhibit may be for the purpose of showing the distribution of corresponding implements over different geographical areas. These and similar special exhibits are instructive, and under proper restrictions should be made; but unless the design of each exhibit is clearly explained, the average visitor to a museum will be confused and misled, for such objects so grouped convey a different impression than when exhibited with their associated objects in proper geographical sequence.

The anthropology of America is now being investigated, and the results are being made known through museums and publications as never before.

The thoroughly equipped Jesup North Pacific Expedition, with well-trained anthropologists in charge, was organised for the purpose of obtaining material, both ethnological and archæological, for a comparative study of the peoples of the northern parts of America and Asia. Although only in the third year of its active field work, it has already furnished most important results and provided a mass of invaluable authentic material.

The Hyde Expedition, planned for long-continued research in the archæology and ethnology of the south-west—a successor in regard to its objects to the important Hemenway Expedition —is annually adding chapters to the story of the peoples of the ancient pueblos.

The results of the extensive explorations by Moore of the mounds of the southern Atlantic coast are being published in a series of important monographs.

The Pepper-Hurst Expedition to the Florida Keys has given information of remarkable interest and importance from a rich archæological field before unknown.

The United States Government, through the Bureau of Ethnology of the Smithsonian Institution, has given official and liberal support to archæological and ethnological investigations in America.

The constantly increasing patronage, by wealthy men and women, of archæological research at home, as well as in foreign lands, is most encouraging.

The explorations in Mexico and in Central and South America, the publication in facsimile of the ancient Mexican and Maya codices, the reproduction by casts of the important American sculptures and hieroglyphic tablets, all have been made possible by earnest students and generous patrons of American research.

The numerous expeditions, explorations and publications of the Smithsonian Institution and of the museums of Washington, Chicago, Philadelphia, New York and Cambridge, are providing the student of to-day with a vast amount of authentic material for research in American and comparative anthropology.

The Archæological Institute of America, the American Folk Lore Society, and the archæological and anthropological societies and clubs, in active operation in various parts of the country, together with the several journals devoted to different branches of anthropology, give evidence of widespread interest.

Universities are establishing special courses in anthropology, and teachers and investigators are being trained. Officers of anthropological museums are preparing men to be field workers and museum assistants.

The public need no longer be deceived by accounts of giants and other wonderful discoveries. The wares of the mercenary collector are at a discount, since unauthentic material is considered worthless. Anthropology is now a well-established science. It is required of those who follow any of its branches to do so in seriousness and with scientific methods.

With all this wealth of materials and opportunities there can be no doubt that anthropologists will in time be able to solve that problem which for the past half-century has been discussed in this Association—the problem of the unity or diversity of prehistoric man in America.

## *UNIVERSITY AND EDUCATIONAL INTELLIGENCE.*

A LARGE amount of information referring to examining authorities and educational institutions in this country appears in the students' numbers issued by several of our contemporaries. The *British Medical Journal* of August 26 and the *Lancet* of September 1 are almost entirely devoted to descriptions of the various methods by which a student may become a fully qualified practitioner. The *Chemical News* of September 1 gives a list of British universities and the chief colleges, technical schools, and institutes. The *Chemist and Druggist* of September 2 contains particulars of the educational requirements for qualification in pharmacy, medicine, dentistry, and veterinary surgery.

SOME time ago a departmental committee was formed to report as to the buildings and site of a proposed new Royal College of Science for Ireland. It is now announced by the *Times* that the Government have arranged to acquire the whole of the house property and ground occupying the site recommended by the departmental committee in addition to the buildings mentioned in the report. The total area thus acquired amounts to over 50,000 superficial feet, and the new buildings will have a frontage both on Kildare Place and Upper Merrion Street, and will, as the report recommends, be in immediate connection with the Museum of Science and Art.

THE West Ham Municipal Technical Institute is one of the newest of the London Polytechnics, and the first session of full work will commence towards the end of the present month. The Institute has been built by the Council of the County Borough of West Ham at a cost of 45,000*l*., and a further sum of 15,000*l*. has been spent upon the equipment and fittings. Under the direction of the principal, Mr. Albert E. Briscoe, an admirable programme of classes has been prepared; and a glance through it shows that provision has been made for theoretical and practical instruction in most branches of pure and applied science and art. Every effort appears to be made to encourage students to use wisely the educational facilities which the Institute affords. As an instance of the excellent policy which is being pursued, the following extract from the "Program" just published is noteworthy:—"Trade students are urged not to make the mistake of joining trade classes only. If any thorough knowledge of the principles of their trade is to be gained, they must possess an acquaintance with elementary science, and have some knowledge of arithmetic, mensuration, and elementary mathematics. For example, very little progress can be made in building or engineering drawing without some knowledge of elementary geometry; plumbing and engineering students will not obtain a clear grasp of their work unless they have some knowledge of elementary physics, of arithmetic, and elementary mathematics. They are further advised to pursue thoroughly the study of one or two subjects, and not waste their energies by attempting to cover the whole ground of science, and so obtain only a smattering of knowledge. The advantage of systematic study in science lies not so much in the number of facts learnt as in the training in habits of accuracy of work and thought, that enables men to attack new problems as they present themselves in a manner likely to ensure their successful solution." Much may be hoped from a Polytechnic in which such sound educational principles are impressed upon the students.

## *SCIENTIFIC SERIALS.*

*American Journal of Science*, August.—Rotatory polarisation of light in media subjected to torsion, by A. W. Ewell. The difficulties encountered in the choice of a proper material for experiment are very great, as already pointed out by Verdet and Wertheim. The author found a satisfactory combination in jelly supported in rubber tubes, and the observations with jelly, corroborated by a few observations with glass, demonstrate that torsion of a cylinder produces the rotatory polarisation of a ray proceeding in a direction parallel to the axis of the cylinder, the rotation of the plane of polarisation being opposite to the twist, and a function of the twist of degree higher than the first.—Studies in the Cyperaceæ xi., by T. Holm. This article deals with the abnormal development of some specimens of *Carex stipata*, Muhl., caused by *Livia vernalis*, Fitch.—The constitution of tourmaline, by F. W. Clarke. The author discusses the respective merits of Penfield and Foote's formula for tourmalines, regarded as salts of the alumino-borosilicic acid, $H_{11}Al_3B_2Si_4O_{21}$, and his own derivation from the similar acid, $H_{14}Al_5B_3Si_6O_{31}$, with all of the hydrogen atoms replaceable by bases. He retains the general form of his own formula, but suggests that certain irreducible differences of constitution may be due to the fact that there exists a series of borosilicic acids.—Determination of tellurous acid in the presence of haloid salts, by F. A. Gooch and C. A. Peters. In the estimation of tellurous acid by oxidation with excess of potassium permanganate, no correction

is necessary when the tellurous oxide is dissolved originally in an alkaline hydroxide and the solution made acid only to a limited degree with sulphuric acid.—An iodometric method for the estimation of boric acid, by L. C. Jones. The method is based upon the employment of mannite and of a mixture of potassium iodide and iodate.—A method for the detection and separation of dextro- and lævo-rotatory crystals, by D. Albert Kreider. The method is based upon the use of a kind of polarimeter with a wide field of vision of a uniform colour, adjusted in such a manner that any small crystal instantly reveals the sense of its rotation by its colour when brought into the field.—New meteoric iron found near the Tombigbee River, Choctaw and Sumter Counties, Alabama, by W. M. Foote. The fall consisted of a series of pieces found in almost a straight line north and south along a nine-mile stretch of the public road.—Orthoclase crystals from Shinano, Japan, by C. Iwasaki. Describes four different classes of orthoclase, mostly twinned after the Baveno type.

*Wiedemann's Annalen der Physik und Chemie*, No. 7.—Smallest thickness of liquid films, by K. T. Fischer. The author brings the widely varying results of various observers into approximate harmony by supposing that when a drop of oil is placed on a surface of pure water, a "precursory film" spreads over the water first, and is followed at a slower rate by the film studied by Sohncke and others. For his own experiments the author used a pure mercury surface, which he found to possess various advantages.—Wehnelt's electrolytic interrupter, by A. Voller and B. Walter. The hydrogen lines are very pronounced in the spectrum of the Wehnelt spark. Intense and pure metallic spectra may be obtained by choosing the metal in question as the substance of the anode. The hydrogen lines do not interfere, but serve as lines of reference.—Kathode rays, by A. Wehnelt. The author distinguishes between two classes of kathode ray shadows. One class is produced by rays emerging from the kathode normal to its surface and crossing each other at a focus in the case of a curved kathode. The other class consists always of upright shadows, thrown by rays travelling in a direction parallel to the axis of the tube.—Cause of the change in the conductivity of a metallic powder, by T. Sundorph. The author proves the formation of connecting chains of particles in a coherer by sparking across the gap between two metallic blocks on a glass plate, with a layer of nickel or iron filings between them.—A new vacuum discharge phenomenon, by L. Fomm. A vacuum tube is surrounded by wire rings at its two ends. At a certain exhaustion blue rings appear, concentric with the wire rings, and enclosing patches of positive light, which gradually disappear until the blue light fills the whole cross section. As the pressure diminishes still further the blue light detaches itself from the glass walls, and expands longitudinally, forming a greenish-blue beam which proceeds in the direction of the other ring, and shows all the properties of kathode rays.—Some experiments with Wehnelt's interrupter, by E. Lecher. The author describes some beautiful phenomena obtained by bringing the secondary spark discharge of a Wehnelt interrupter into a magnetic field. The secondary current is unidirectional, and is therefore deflected in a constant direction. When the discharge takes place between a circle of wire and a disc mounted in its plane, and concentric with it, the discharge consists of curved spokes of light which rotate rapidly, in a sense governed by the polarity of the magnet. The discharges form a kind of fire-wheel as displayed in pyrotechnics.

## SOCIETIES AND ACADEMIES.

### PARIS.

**Academy of Sciences**, August 28.—M. Michel Lévy in the chair.—On the general form of the equations of dynamics, by M. P. Appell. The advantage of the form of equation described is that it allows the use of parameters which are not true coordinates, but are connected with the coordinates by non-integrable differential relations. The method is of especial service in problems of rolling.—On the velocity of detonation of acetylene, by MM. Berthelot and Le Chatelier. Acetylene was detonated in a glass tube by caps of mercury fulminate or chlorate powder, care being taken to have the detonator as small as possible, as it was found that irregularities were introduced if the detonator used was too violent. The acetylene was contained in horizontal glass tubes, under pressures varying from 5 to 36 atmospheres, and the velocity was registered photographically upon a falling sensitised plate, the light emitted by the explosion itself being sufficient for the purpose. As the flame moved further from the source of explosion the velocity continually increased, the tube generally breaking before the speed became uniform. Even when the conditions of inflammation and pressure are apparently precisely identical in two succeeding experiments, discordant results were sometimes obtained for the increase of velocity of the flame along the tube. The results show that the propagation of the detonation of acetylene is produced with a velocity which increases with the pressure from 1000 metres per second at 5 atmospheres pressure to 1600 metres per second at 30 atmospheres.—M. Henri Moissan communicated to the Academy a letter he had received from Prof. Dewar, of London, in which details were given of the solidification of hydrogen. Solid hydrogen melts at 16° absolute (−257°), and at this temperature helium is liquefied under a pressure of 8 atmospheres.—Discovery of a new planet at the Observatory of Paris, by M. Jean Mascart.—The Perseids in 1899, by M. C. Flammarion. The tabulated list is accompanied by a chart showing the point of origin and direction of motion of the Perseids in 1899.—On beats given by vibrating strings, by M. C. Maltézos. The ordinary equation for a thin elastic string giving the relation between the number of vibrations, tension, section, and length of string gives no explanation of the phenomenon of beats. If the rigidity of the string be taken into account, the author theoretically deduces an expression for the number of vibrations from which can be deduced that the number of beats is proportional to the square root of the area of section, inversely proportional to the cube of the length, and inversely proportional to the square root of the tension. The last conclusion has been verified experimentally, but instead of the number of beats being inversely proportional to the cube of the length of the strength, it is nearly inversely as the length simply. Hence it is impossible from rigidity alone to explain all the phenomena of beats in vibrating strings.

THURSDAY, SEPTEMBER 14, 1899.

## *THE CORRESPONDENCE OF HUYGENS.*

*Œuvres complètes de Christiaan Huygens publiées par la Société Hollandaise des Sciences.* Tome Huitième. Correspondance 1676–1684. Pp. 629. 4to. (La Haye: Nijhoff, 1899).

EXACTLY a year after the seventh volume of Huygens' correspondence the eighth one has made its appearance. As it embraces nine years, and Huygens only lived ten years longer, we may expect that the ninth volume will be the last one devoted to his correspondence. The objection which we made a year ago to the many comparatively uninteresting private letters which have contributed so much to the huge extent to which this collection has grown, applies equally to the present volume. No doubt Huygens was very glad to get the pleasant, gossiping letters from his sister Susanna, who kept him up to what was going on in Holland during his stay in Paris, but posterity will hardly be equally grateful to the far too conscientious editors who have considered it a duty to insert them among Huygens' "Œuvres complètes." One feels momentarily almost kindly disposed towards the niece of Peiresc, who ruthlessly destroyed ten thousand letters found after him.

Having suffered from ill-health for some months, Huygens left Paris for the Hague in the summer of 1676. In the autumn of the following year he wrote to Colbert to apologise for not coming back that winter owing to his health, but it appears from a letter to his brother Constantin that this was a mere excuse. To his absence from Paris at this particular time we owe some very interesting letters, exchanged between him and Roemer about the latter's discovery of the gradual propagation of light. Huygens had to return to Paris in the summer of 1678, as he did not wish to lose his French pension, but in 1681 he bade a final farewell to Paris and established himself in his native country. It has been generally supposed that he and Roemer (who had left the French capital a few months before him) were induced to do so by the feeling that Protestants were about to have a bad time in France, though as a matter of fact the edict of Nantes was not repealed till four years later. No doubt this feeling may have had something to do with their departure, but we learn from his correspondence that Huygens did not debar himself from returning, but kept a door open by writing from time to time to Colbert, and after his death to Louvois, regretting that the necessity of being near skilful workmen prevented him from returning yet, and expressing the hope that his pension might not be finally withdrawn. Doubtless he spoke his mind more honestly when he wrote to Constantin (September 1682) that he had no intention of living in France, partly on account of the three illnesses he had suffered from there, "and also for other reasons," but that he wanted to try to get some part of his pension without living in France. From the very last letter in the volume we see that he was in December 1684 still pegging away at Louvois, but the Minister of War of Louis XIV. no doubt considered that money was too scarce to be spent on a foreign philosopher.

The skilful workmen, whom Huygens wanted in 1681 were required for the completion of his planetary machine, by which he claimed to represent the motions in the solar system with considerable accuracy. Huygens was very proud of the performance of this machine, which is still preserved at the Leiden Observatory, and in letters to Colbert and others he repeatedly lays stress on its superiority to the machine for the same purpose constructed by Roemer, which is also still in existence, in the "Round Tower" at Copenhagen, on the top of which the observatory was formerly situated. While working at this machine Huygens also wrote to Paris that he was engaged in the perfection of time-keepers for finding the longitude, and that he did so at the instance of the East India Company, but we hear nothing further about this matter. After his return to Holland he and Constantin resumed their investigations on the best methods of polishing lenses for telescopes, and in a number of letters they exchanged their ideas as to the proper construction of polishing machines, &c. In 1684 Christian Huygens published his "Astroscopia compendiaria," in which he described his method of using very long telescopes without tubes, keeping the eye-piece in the optical axis of the object-glass by means of a long string which connected two rods attached one to each. In a letter dated June 5, 1684, J. D. Cassini makes the very remarkable suggestion that the object-glass might be moved by a monster clock moving in the plane of the equator, on which for the hand was substituted a perpendicular plane to which the lens might be attached according to the declination of the star. We believe this to be the earliest suggestion of an equatorial moved by clockwork. On the other hand, Perrault, a month later, sent Huygens a design of a horizontal telescope into which the light from the star was thrown by a mirror kept in the proper position by an assistant, who pointed to the star with a small altazimuth tube connected with the mirror by a system of pulleys. He also sent a similar design by a certain Boffat. It is interesting to see that the horizontal telescope has been proposed so long ago.

During the period (1676–84) covered by the present volume several discoveries of the highest importance were given to the world, especially the discovery of the differential calculus by Leibnitz, but the communications exchanged between him and Huygens on this subject have already been printed in the collections of Uylenbroek and Gerhardt. Quite new, on the other hand, are the letters on Roemer's discovery of the gradual propagation of light, only the two first of which have been printed before (in Horrebow's "Opera mathematico-physica," T. iii. pp. 126–127, apparently not noticed by the editors). In reply to an inquiry from Huygens, who had seen in the *Phil. Trans.*, No. 136, a short account of Roemer's paper (laid before the Academy on November 22, 1676), Roemer informed him, under date September 30, 1677, that Picard acknowledged the reality of the discovery, but that Cassini did not, as only the first satellite of Jupiter showed the phenomenon. Roemer explained this by pointing out that the occultations of the outer satellites were less frequent, the moments of their occultations less sharply observable owing to the

slower motion and to their generally entering the shadow more obliquely; their inclinations and nodes were less accurately known, while it was well known that the motions of the outer satellites differed in a very irregular manner from Cassini's tables by amounts much larger than that dealt with in the case of the first satellite. The deviation in question was neither a function of the anomaly of Jupiter nor of that of the earth, nor of the configuration of the satellites, but solely of the distance from the earth. Writing to Colbert shortly afterwards, Huygens calls the discovery a most important one, in the confirmation of which the Royal Observatory would be worthily employed, and he adds that he was all the more pleased, as he had himself already, by means of this hypothesis, demonstrated the laws of the double refraction in Iceland spar. To Roemer he wrote that Cassini's objection did not trouble him much, as long as there were not better ephemerides of the outer satellites available. He doubted that observations of the surface-markings of Jupiter would be of any use in this inquiry, as they could not be accurate enough; but this Roemer did not acknowledge, since the time of passage of a spot across the central meridian could be fixed within two minutes. In a subsequent letter and in a communication to the Academy (which does not seem to have been printed before), Roemer proudly gives observations of a spot of September and December 1677, the comparison of which with an assumed value of the period of rotation seemed to exhibit the phenomenon beautifully. Of much greater interest is a remark made by Roemer in a letter dated December 30, 1677, in which he points out that the motion of the earth must affect the apparent direction of the path of light! In Cartesian language, he expresses this by saying that the circular motion of the terrestrial vortex must produce a curvature of the path, and he ingeniously suggests that the amount of this deflection might be determined by selecting two stars in the zodiac, nearly opposite each other, and observing their angular distance apart, first when one was at its heliacal rising, and again four or five months later when the other approached its heliacal setting. The difference would be four times the amount of the deflection, or, as we should say, four times the constant of aberration. It is very remarkable that Picard, Roemer's teacher and friend, should have discovered the changes in the place of the pole-star due to aberration (and also those due to nutation, though not the laws which regulate either—see his "Voyage d'Uranibourg," article viii.), while Roemer logically concluded from his discovery of the velocity of light that there ought to be aberration of light. But it was reserved for Bradley to publish both the laws and the theory of aberration. These facts become still more curious when we reflect that, but for the unfortunate destruction by fire of almost all Roemer's observations—which had been made with instruments constructed on novel principles not adopted elsewhere till much later, the foundation of modern astronomy might have been built on them and not on Bradley's observations. It was indeed unfortunate that Roemer published so very little about his scientific labours, and it is therefore particularly interesting to get a slight insight into them through his correspondence with Huygens.

Among other matters dealt with in this volume we may mention the controversy on the theory of the centre of oscillation between Huygens and Abbé de Catelan, a man whose aim in life seems to have been to object to every new mathematical publication and to exhibit his inability to grasp any new theory. In Vol. i. of Huygens' "Opera varia," the papers written by the two opponents, as well as by Jacques Bernouilli, who took Huygens' part, have already been printed side by side; but it is interesting to see from the correspondence that Catelan's attack was slyly inserted in the Amsterdam reprint of the *Journal des Sçavans*, although it had not appeared in the original Paris edition.

The volume contains as frontispiece a plate reproducing a fine medallion of Huygens from 1679, and another showing a medal apparently struck in his honour in the same year. It is announced that his unpublished works are to appear in the volumes following immediately after those devoted to his correspondence.

J. L. E. DREYER.

## *METAPHYSICS OF BIOLOGY.*

*The Living Organism: an Introduction to the Problems of Biology.* By Alfred Earl, M.A. Pp. xiii + 271. (London: Macmillan and Co., Ltd., 1898.)

THE observer of the more recent phases of biological thought will not need to be told that during the last few years a reaction has been setting in, both in England and abroad, against any so-called mechanical theories of the origin and development of living things, and against any hypothesis which seeks in the facts of chemistry and physics for an ultimate explanation of the phenomena of life; and those who have had the opportunity of a more intimate acquaintance with this new philosophical development will know that the "neo-vitalist" adopts, as the basis of his scientific beliefs, an ontology which states that it is not true that the hierarchy of the natural sciences presents us with a material universe of which the separate parts studied by the several sciences can all be ultimately expressed in terms of one of them, biology in fact being a special case of chemistry, this of physics and so on; but that on the contrary every science deals, not with a part, but with the whole of the material universe, all the facts of which come under its survey, and as a particular manner of looking at which it is to be regarded. On this view, therefore, it is as useless ever to expect a physical explanation of the chemical atom as it is futile to hope that organic metabolism may after all turn out to be merely a specially complex chemical reaction: each science has what is, for itself, an ultimate fact, in terms of which it seeks to express the whole of nature, but which has nothing in common with the ultimate fact of any other science whatever. This ultimate fact is, for the vitalistic biologist, the living organism, and when pressed for an account of how the inanimate world is included in his science, he replies by a reference to the environment, which, we are told, is to be regarded as being made by and for the organism itself.

Now it may be that the ontology which includes, with Kant, all phenomena in but a single category is obsolete,

as these philosophers suggest, and that we must rather, with Hegel, look upon the universe from several points of view, though even Hegel, if we are not mistaken, would have made the various categories develop out of one another; but whether that be so or not, and however impossible it is at present to point to any scientifically complete demonstration of the correctness of the opposite hypothesis, it is necessary to inquire very carefully into the positive basis on which this revived vitalism, of which the present volume is an exposition, rests.

Starting with sundry somewhat loosely connected remarks on the nature of knowledge in general, and the method of biology in particular, the author, after giving a brief account of the functions of assimilation and reproduction in the living organism, touches, in a chapter on the relation of that organism to its surroundings, the key-note of his whole system. Since, we are told, the human organism is a knowing subject, the organism in general is to be regarded as not only object but also as subject; and hence all mechanical, or physical, or chemical explanations of organic function are and must ever be inadequate, because they take no account of that inexplicable residuum, the "spontaneous choice" or "selection," the "subordination to a purpose" which an organism displays in every function it performs, and most obviously of all in sensation, the act which puts it in immediate communication with its environment.

Now such a view as this seems to us to be pervaded by a most vicious anthropomorphism, due to an unfortunate confusion between the organism, or its nervous system, to which those parts of the phenomenal world outside it are related during the act of knowledge, on the one hand, and on the other the metaphysical *ego* or subject of knowledge. For knowledge is most certainly not, as the author seems to imagine (for he tells us that knowledge is part of the subject-matter of biological science) a relation between the organism and its environment, both of which are phenomenal, that is to say are events occurring in space and time, but a relation between phenomena and a timeless and spaceless noumenon, with which metaphysics alone is concerned, but with which science has nothing to do at all.

The endeavour to locate in the organism, regarded as matter for scientific inquiry, a "subjective" residuum is apt to remind one of the now discredited search for that metaphysical phantom, the "thing-in-itself," and it is incumbent upon biology, advancing along rigidly deterministic lines, to resist any attempt to transfer that "freedom of the will" which psychology cannot allow for the human organism, under the name of "spontaneous selection," to the purely objective phenomena exhibited in organic function.

There are, indeed, no grounds either in theory or in fact for regarding the organism as anything else but the transitory product of certain causes which it is the aim of the biologist to discover. When Mr. Earl speaks of constant form under an ever-changing material, he momentarily forgets the dominant fact of the evolution of form; and to whatever causes we assign this evolution, its existence is beyond a doubt; and when he speaks of the impossibility of applying quantitative conceptions to organic phenomena, he either ignores or is ignorant of certain recent work in this direction, in which, indeed, alone lies a hope for the progress of biology as a science.

Serious though the misconceptions seem to us to be which mar this essay, apart from certain minor details of arrangement to which exception might possibly be taken, and the mistake of discussing epistemological problems in a book apparently intended for beginners, we may at least hope that it will serve to convince those who may still be in doubt of the futility of attempting to apply to the living organism, which, like the subject-matter of any other science, should be studied from a strictly ætiological point of view, teleological conceptions which have not even a place in human psychology. Not that it is therefore to be supposed that when the sciences have said all they have to say our knowledge of the universe is at an end: the last word must always remain with metaphysics, in which those ideas of "freedom" and the "final cause" which science cannot accept may find their true proportions; for metaphysics looks upon the universe not merely as a continuous time-process, but as a whole, time and space being only the forms under which phenomena appear to a transcendental subject, in which the ultimate interpretation of them is to be sought, but which it is as fatal for metaphysics as it is for science to confound with the living organism.

## OUR BOOK SHELF.

*An Account of the Deep-Sea Ophiuroidea collected by the Royal Indian Marine Survey Ship "Investigator."* By R. Koehler. (Calcutta: 1899.)

This monograph, published by order of the Trustees of the Indian Museum, is well worthy its predecessors, now famous, and adds one more to the brilliant results of the *Investigator*, memorably associated with the names of Dr. A. Alcock, its editor, now superintendent of the Indian Museum, and his indefatigable co-workers in the Zoology of the Indian Seas. It is chiefly devoted to the description of forty species of Ophiurids which are new, the majority of the larger number obtained during the cruises of the ship having been already reported upon by Prof. Koehler in the *Annales des Sciences Naturelles*, as explained in the text. The new forms are of the genera *Ophiacantha* (7 species), *Amphiura* (5 sp.), *Ophioglypha* (4 sp.), *Ophiomusium*, *Ophiactis*, *Ophiochiton*, *Ophiomitra*, and *Gorgonocephalus*, each 2 sp., and thirteen other genera each 1. Interest chiefly centres in a new genus, *Ophiotypa*, obtained in the Gulf of Bengal at 1997 fathoms. *O. simplex* is the name by which the author would have it known, its special structural peculiarity being the great size of the primary plates of the disc, the aboral region of which is beset by an enormous pentagonal centro-dorsal and five equally large radials, separated by small but regular inter-radials. Interbrachial plates are present on the ventral face. Radial shields are absent, and the author, regarding this character and the small number of plates present in the disc of the adult as primitive, proceeds to a comparison with the young stages of *Amphiura*, as described by Ludwig and Fewkes, which would seem to justify the conclusion that *Ophiotypa*, as regards its skeleton, may be a persistently embryonic form.

The monograph is elaborately illustrated by fourteen exquisite plates, photo-etched from the author's drawings at the Survey of India Offices in Calcutta, and on perusal of its contents the mind reverts to the interesting series of Astrophiurids, whose "primary larval plates" and

growth stages were in 1884 described and discussed by Sladen, and conjures up theories of stalked-ancestry, pentameral symmetry, and the like. Whatever the significance of the facts, this beautiful report comes to us at an opportune moment, *à propos* of the issue of the magnificent series of "Illustrations," delineating the many novel forms discovered and described by Dr. Alcock and his co-workers in the Indian seas during the last nine to ten years. He has shown by his own share of the work that it is possible for one man, new to the task of marine investigation, to successfully handle taxonomically groups so dissimilarly ordained as the Bony Fishes and Echinoderms, to say nothing of his sterling work upon the "Carcinological Fauna" of the area. An achievement this of which he may well be proud. The *Annals and Magazine of Natural History* and *Journal of the Asiatic Society of Bengal* for the period named teem with his original communications, and to him, to Commanders Carpenter, Hoskyn, and Oldham, to Dr. A. S. Anderson, who has more recently taken up the work, their collaborators, assistants, and native artists, we tender our hearty congratulations upon the skill and persistent patient enthusiasm with which they have so long and so successfully continued their task. Work thus performed is always durable, and that of H.M. Survey ship *Investigator* will be ever conspicuous among post-Challengerian explorations of the deep sea.

We close the report with a feeling of gratitude to all concerned in its production.

## LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

### Dark Lightning.

I HAVE been greatly interested by some photographs showing the rare phenomenon of dark lightning, which have recently been sent to me. So far as I know the only explanation that has ever been offered to account for them is photographic reversal, due to extreme brilliancy. This appears to me to be wholly out of the question for two reasons. In the first place, a dark line on the picture, resulting from over-exposure of a very brilliant line, would be surrounded by bright edges due to the lesser photographic action in the halation region. This is never present so far as I know, the dark flashes being minute black lines ramifying from, or in the neighbourhood of, the main discharge. Secondly, from what evidence I can gather, the dark parts of the flash are not those which appear most brilliant to the observer. Mr. Jennings, of Philadelphia, who in 1890 secured a remarkable picture (reproduced in *Photog. Times Annual*, 1891) showing a very brilliant flash with countless dark flashes covering the sky around it, tells me that the appearance to the eye was a brilliant white discharge, with fainter rose-coloured ramifications, the latter developing in the negative, or rather positive, as dark flashes.

Some years ago it occurred to me that a dark flash might be produced by a preponderance of infra-red radiations, which, as Abney has shown, undo the work of ordinary light on the plate. If we had a form of discharge capable of giving off very little actinic light, and an abundance of infra-red light, it might come out dark on a feebly illuminated background. This is of course a very wild guess, with nothing to substantiate it; but the dark flash appears to be a reality, and a poor hypothesis is perhaps better than none at all. I have recently thought that the phenomenon might perhaps be explained in another way.

We have a flash which appears darker than the sky behind it. It is inconceivable that the discharge could render the air in its path opaque, in the ordinary sense, to white light. But the light which illuminates the sky, in the case of these pictures, is not daylight, but light coming from another flash, that is made up of wave-lengths corresponding to the periods of vibration of the dissociated matter in the path of the discharge. Now, may it not be possible that in the dark flash we have a discharge, weak or nearly wanting in actinic light, which, however, renders the air in its path capable of absorbing to some extent the radiations of the wave-lengths which come from the bright flash?

Such a flash might possibly appear dark on a background feebly illuminated by light, exclusively of these wave-lengths. In other words, may we not have in the path of the dark flash dissociated molecules, radiating but feebly, and capable of taking up vibrations of periods similar to their own, coming originally from a simultaneous brighter discharge?

It might not be impossible to reproduce the phenomenon by photographing a spark in front of a light background. Sparks are almost always taken against a black background, which would account for the absence of dark flashes in pictures of artificial discharges. A heavy main spark with lateral branches would seem the most suitable kind to employ.

The best method of attacking the problem experimentally, it seems to me, would be a search for selective absorption in a partially exhausted tube.

If the source of light were continuous, any absorption would be unnoticeable, unless persisting for some time after the discharge (which is unlikely), for the time between successive discharges is great in comparison to the actual duration of one of them. Even in the case of so-called continuous discharges produced by high potential batteries, the discharge is often, and may always be, intermittent in character. The source of light should then be of no longer duration than the discharge occurring in the gas the absorption of which is to be examined.

I can think of no way of producing a white or continuous spectrum source of as short duration as, and contemporaneous with, the discharge in the tube, but by employing two tubes differently excited, the one as a light source, the other as an absorption tube, some results might be obtained.

Prof. Trowbridge found that an argon tube emitted a blue light or red light according to whether it was illuminated by means of an oscillatory or non-oscillatory discharge.

By using the blue tube as the source of light and the red tube as the absorption tube, the two being arranged so as to be illuminated simultaneously, it might be found that the red tube had the power of absorbing, to some extent, the blue radiations from the other.

I hardly think results would be obtained, but the experiment seems worth trying.

A picture taken by Mr. H. B. Lefroy, of Toronto, sent to me by Mr. Lumsden, Secretary of the Astronomical and Physical Society of Toronto, has some very curious appearances. There is an exceedingly brilliant flash running down the centre of the plate, illuminating the sky quite brilliantly in its neighbourhood. In its immediate vicinity, though not joined to it in any way, are innumerable dark, thread-like markings, which in places seem to cross each other, forming meshes. Mr. Lumsden assures me that the testimony of all photographic experts who have seen the plate is to the effect that markings of that description could only be produced in the exposure—that is, they are not due to faults in the film or the results of imperfect development. The fact that they are found only in the immediate vicinity of the bright flash is additional testimony in the same direction. These markings are wholly different from any that I have seen, not having the form of branched flashes. Something in their resemblance to photographs of sound-waves started by a spark, which I have recently made (see *Phil. Mag.* for August), suggested to me that they might possibly be due to the illumination of the sound-wave due to a powerful discharge by a second discharge. Under ordinary conditions, that is, with a uniformly illuminated background, such waves would of course be invisible, but conditions might possibly arise due to the proximity of black clouds under which they might show—a sort of "Schlieren Methode" on a large scale. I have not attempted yet to plan an arrangement of clouds, which, by acting as screens to light coming from certain directions, might render visible a region of the air in which the optical density underwent a rapid change.

Mr. Lumsden's picture shows very black clouds irregularly distributed and in close proximity to the flash.

The idea of a photograph of a thunder wave is a pleasing fancy, at all events.

It seems to me that it will be impossible to formulate even a reasonable guess as to the cause of these dark flashes until a good many pictures are brought together for comparison, and as much testimony as possible secured as to the appearance of the flashes to the eye. Personally I have seen very few of the pictures, and never the original negative.

My intention in writing this letter is not so much to advance theories accounting for the phenomenon of the dark-flash as to reawaken an interest in the subject, and bring out ideas from persons qualified to treat the matter.

Madison, Wisconsin, U.S.A. R. W. WOOD.

## Tides in the Bay of Fundy.

IN the last report of Mr. W. Bell Dawson on the Survey of Tides and Currents in Canadian Waters, the results are given of an investigation of the tides in the Bay of Fundy. The information in Mr. Dawson's report is interesting, as these tides are frequently credited as having the greatest range of any in the world, and in some books of physical geography are stated as having a range of 120 feet,[1] or more than double that which actually prevails.

As a matter of fact the range of the tides in the Bay of Fundy does not exceed that which occurs in the Bristol Channel, where the extreme recorded difference between high and low water at Chepstow is 53 feet, being the same as the "Saxby," or record tide in the Cumberland Basin, Nova Scotia. The rise above the mean level of the sea in both cases is about the same, or from 22 to 23 feet.

In the Bay of Fundy the range varies considerably at different localities. Outside the bay at Portland on the north side the range is 9½ feet, and at Cape Sable on the south side 8½ feet. In the Atlantic, on the south side of Nova Scotia, the range is from 6 to 7 feet. At the mouth of the bay at Yarmouth the range is 16 feet, and at Seal Island 18 feet. Further up, at Digby, on the south side, and St. John on the north, it increases to 27 feet. Where the bay divides above Black Rock the range is 36 feet. In the Minas Basin it varies from 41 feet at Parsboro to 48 feet at Horton Bluff and 50½ feet at Noel Bay. In the Chignecto Channel in Cumberland Bay the range is 45½ feet.

From observations obtained by tide gauges fixed at different stations, and information collected in the localities, Mr. Dawson gives the range of spring tides as follows.

The highest recorded tide is known as the "Saxby tide," which occurred in 1869. The low water mark for that tide is not given, but taking the lowest low water level recorded, the range of that tide in Cumberland Bay was 52·80 feet; the ordinary spring tide range there being 45·80 feet. The Admiralty tide tables give this as 45¼ feet.

At Moncton, the Saxby tide rose above the lowest recorded level, 38·34 feet; the next highest recorded tide being in 1887, 31·91 feet. An ordinary spring tide rises 30·25 feet above mean low water of spring tides. The Admiralty tide tables give the range at Moncton Railway as 47 feet. Mr. Dawson points out that this is misleading, this range being that above low water at the mouth of the river, from which the low water line has a considerable inclination towards the head of the estuary.

At Parsboro, in the Minas Basin, the ordinary spring tide range is 41 feet, and the extreme 47 feet; the Admiralty tide tables giving the ordinary range as 43 feet.

Mr. Murphy, the Provincial Engineer of Nova Scotia, in a paper contributed in 1867 to the Institute of Natural Science, on the tides in the Bay of Fundy, gave the range of spring tides at the head of the bay as 22 feet above mean sea level, and as varying from 50 to 60 feet above extreme low water.

Having a few years since to report on some proposed embankment works in the Bay of Minas, I made inquiries in the locality from those best able to furnish me with information as to the rise of the tides there, and came to the conclusion that at Horton the greatest range to be dealt with was 48·50 feet.

The difference in the range of the tides in Cumberland Bay, at the head of the Bay of Fundy, and in Verte Bay, Northumberland Straits, in the Gulf of St. Lawrence, is worth recording. The length of the isthmus which separates the two bays along the line of the proposed Chignecto Ship Railway is eighteen miles. The range of ordinary spring tides on the one side of this neck of land is 45·80 feet, and of the highest known tide 52·80 feet; and on the other side 13·40 feet and 5·60 feet respectively, the mean level of the sea being only 0·26 feet higher in the Cumberland Bay than in Bay Verte.

It is interesting to compare the tides in the Bay of Fundy with those in the Bristol Channel. At Bude Haven and Pembroke, at the mouth of the Channel, the rise of an ordinary spring tide is 23 feet; at the mouth of the Avon it is 40 feet; at Chepstow the range is 50 feet, and in extreme tides 53 feet, the rise above the mean level of the sea being 23½ feet. From levels taken across the land from Portishead in the Bristol Channel to Axmouth in the English Channel, with a mean tide rising 35½ feet at Portishead and 10 feet at Axmouth, the mean level of the sea was found to be 9 inches higher at the former than at the latter place.[1]

There is a tidal bore in the Bay of Fundy, but it is not so strongly developed as at some other places. It shows itself at Moncton, 19 miles from the mouth of the Petticodiac River, where the estuary consists, at low tide, of mud banks and flats, with a low water channel about 500 feet wide, and having at high water a width of half a mile. The run of the rising tide first breaks into a bore at Stoney Creek, 8 miles below Moncton, and continues to the head of the estuary at Salisbury, 13 miles above, the total distance traversed being 21 miles. Mr. Dawson describes the noise made by the approaching bore as that of a distant train, which increased to the hissing and rushing sound of broken water. The bore arrived at the point of observation eleven minutes after the sound was first heard, having the appearance of a front of broken and foaming water 2 to 3 feet in height. The mean velocity was 8·47 miles an hour, the maximum being 9·61 miles. The greatest rise of water after the bore passed was 3 feet in ten minutes. The greatest recorded height of the bore is 5 feet 4 inches.

The only other place in the bay in which a bore has been observed is in the upper part of Cobequid Bay.

W. H. WHEELER.

## *ETHNOGRAPHICAL COLLECTIONS IN GERMANY.*

THE question of the representation of primitive culture in our national museums is rapidly becoming an urgent one, not only on account of the growing importance of anthropology, but also because primitive culture itself is disappearing before civilisation. The wild man is dying out or being transformed, and the hours during which we may question him about himself are already limited. Those nations therefore which take the utmost advantage of the opportunities which remain will have something in the nature of a monopoly when primitive culture is actually extinct; and it is to them that the students of the twentieth century will have to apply for their facts.

If her present rate of progress is maintained, Germany will soon have so far distanced all other European countries as to place herself in a position of permanent and unassailable superiority. It cannot therefore but be a matter of importance to cast a glance at the present state of ethnographical museums in Germany, in order that we may form some notion of the relative position of our own.

Almost all the large cities in the German Empire possess ethnographical collections, and in such places as Leipzig, Dresden and Hamburg, these are of first-rate

[1] In Sir J. F. Herschell's "Physical Geography of the Earth," fifth edition, 1875, it is stated that: "In the Bay of Fundy the tide not commonly rises 50 feet, and, as is said, on some occasions to more than double this height." Robinson, in his "Mechanical Philosophy," in the article on Tides, says, "In the Bay of Fundy, in the harbour of Annapolis Royal the tide rises 120 feet."

[1] "Tidal Rivers." (Longman's Engineering Series, 1893.)

importance. But none of them are in the same class with Berlin, and as it is with Berlin that London ought to measure itself, these short remarks must practically be confined to the German capital.

The Königliches Museum für Völkerkunde is a large building completely devoted to ethnographical and prehistorical collections: it has three floors, the lowest devoted to prehistory; the first to the collections from Africa, Oceania and America; the second to those from Asia. For administrative purposes it is divided into five departments: the Prehistoric, the African and Oceanic, the American, the Indian, and the Chino-Japanese. Each of these departments has a keeper, who usually has two assistants under him, so that the scientific staff amounts to about twelve men. The museum has an annual grant of 50,000 marks, which is supplemented upon special occasions by the voluntary gifts of a committee of wealthy and patriotic citizens known as the "Hilfskomitée." The value of this unofficial assistance can hardly be over-estimated. It makes possible the acquisition of exceptionally fine collections when the Government grant is not alone sufficient, as in the case of Benin, and it provides the means of retaining scientific explorers and collectors in outlying parts of the world. The museum can thus command the services of well-instructed investigators, and is in a position to carry out the work of collecting in a systematic and continuous manner. Berlin is probably far less dependent on the dealer and the unscientific collector than we are in London. Altogether the Hilfskomitée appears to be a most admirable institution reflecting the greatest possible credit upon all concerned.

The housing of the collections at the Museum für Völkerkunde is also excellent. In addition to extensive basements and a domed hall with a gallery running round it, there are two large and four smaller rooms on each of the three floors. Most of these are lighted from both sides, the objects being exhibited in large free-standing metal cases with glass shelves, so that none of the specimens lie in deep shadow. The wall space between the windows and at the ends of the rooms is thus available for maps and diagrams, of which there are great numbers; there is also room for numerous "mannikins," or life-sized models of representatives of various tribes, all carefully coloured, and dressed and armed in the style of their respective countries. These figures, with excellent models of houses, canoes and other large objects, and with ample and carefully written labels, afford a far more vivid picture of primitive life than can be obtained from books alone. The arrangement of the collections is geographical, but occasionally comparative series, known as "Vergleichende Gruppen," are exhibited; this is especially the case in the Indian Section. A library and a lecture theatre are important adjuncts to the building, and the latter brings the museum into direct connection with anthropological teaching. This has obvious advantages, for it probably enables the staff to stimulate the interest in ethnology of many students who afterwards become connected with Colonial administration.

Enough has perhaps been said to illustrate the advantages which Germany enjoys in the acquisition of ethnographical collections and in the dissemination of ethnological knowledge. Compared with our own, her position is very striking. We have no independent ethnographical museum, for at present we can only use for the purpose a section of the Department of British and mediæval antiquities at the British Museum. The officials of this Department, with so many other claims upon their attention, cannot be expected to compete with the organised staff at Berlin, who concentrate their whole attention on ethnographical studies. Against continuous and systematic collection we can only set occasional and limited acquisitions. Under such conditions, the race between Great Britain and Germany is a race between Argus and a blind man. Nor can we flatter ourselves that we are to be eclipsed by Berlin alone; for Leipzig is already a serious rival, and Dresden is considering the erection of a new museum of ethnography. In numerous other towns there are abundant signs of activity.

If it is asked how it is that the Germans have outstripped us in this manner, several reasons at once suggest themselves. To begin with, the rapid commercial and Colonial expansion of Germany during the last thirty years has been the expansion of the best educated people in Europe. Thus there has been little tendency to regard savage races from the point of view of a popular show, and a widespread capacity to assign to primitive culture its due scientific importance. If this is the attitude of the people as a whole, it is but natural that in officials, travellers and merchants a taste for ethnology is easily awakened. And as these are the classes in which a museum would naturally find its most useful allies, the national collections have greatly benefited by their interest and co-operation. The introduction to the Guide to the Museum für Völkerkunde contains a large proportion of official names in its long list of donors. Naval and military officers, consuls, doctors and administrators, are all conspicuous in their turn. The museum has also enjoyed the support of more exalted personages, for the German Emperors have all given proof of their sympathy upon various occasions. Again, the German museums appear in many respects to be worked more economically than our own. Their hours of closing are early, so that artificial lighting is not required in the galleries; they are also closed during at least one day in each week, which enables scientific studies to be carried on with the minimum of interruption, and the work of cleaning to be executed by a smaller staff. The fittings are also arranged with less regard for high finish than for practical and serviceable qualities. Finally, the wonderful energy and initiative of the veteran Prof. Bastian must not be forgotten. He has pressed the claims of ethnography with untiring enthusiasm for many years, and has had the reward of living to see the museum which he directs take the first place among the ethnographical museums of the world.

Comparisons are proverbially odious, and that which one is compelled to draw between Berlin and London is not gratifying to national pride. It is hard to believe that we can continue satisfied with present conditions, and sooner or later a change must come. Let all scientific men, whether their immediate interests lie in the direction of ethnography or not, lend their sympathy and support to any movement which promises to introduce a new order of things. But the old order must be changed quickly, or it may be too late. Even now it is doubtful whether we can ever make up all the ground which has been lost, for in some parts of the world specimens of primitive art are vanishing with such rapidity that complete collections are perhaps unattainable. But a serious effort made at the present time would be crowned at least with a comparative success; and the first thing to be done is to house in a more satisfactory manner what we already possess. It would surely be desirable to unite under one roof the collections which illustrate primitive culture, and those which illustrate the physical characteristics of the different branches of mankind. Meanwhile it should be freely admitted that we have much to learn from continental nations, for not only Germany but also Holland can give us useful lessons in the ethnographical exploitation of a Colonial Empire. But Berlin is the model which we should set before our eyes: the frank admission of this fact will be the best preliminary to a more satisfactory state of affairs.

## THE DOVER MEETING OF THE BRITISH ASSOCIATION.

IT is hardly yet possible to give anything like an accurate estimate of the number of members likely to be present at the meeting of the Association, but it is probable that there will be at least 1500 visitors. The foreign members of the Association will be well represented. Prof. Chappuis, of Paris, will discuss Thermometry in Section A. It is likely that Prof. Remsen will pay a flying visit to the meeting. Amongst other Americans who have promised to attend are Prof. Rotch, of the Blue Hill Observatory, Prof. Bauer, of the Magnetic and Geodetic Survey, Profs. Barker, Carl Barus, Campbell, Thurston and Scott. Prof. Calmette, of the Pasteur Institute, may possibly attend, but he is at present engaged on the Plague Commission at Oporto: Prof. Kossel, of Marburg, is with him, but hopes to come to Dover if possible. Prof. Kronecker, of Berne, will be also present, so that the foreign physiologists are well represented. Of foreign chemists, besides those mentioned, are Profs. Ladenburg and Fittig and Georges Lemoine. Geography will be represented by Prof. Hjort, of Christiania; Dr. Gerhard Schott, of the Deutsche Seewarte, who will speak on the results of the *Valdivia* Deep Sea Exploration; H. Arctowski, who will read a paper on Arctic Exploration; Admiral Markaroff, of the Russian Navy, will also attend. Abbé Renard, of Ghent, Dr. van Rijckevosel, Prof. Julin, of Liége, Prof. Cyon are a few of the other celebrated foreign men of science who are expected.

The question of accommodation of the visitors has reached a very acute stage, if we may judge from the letters which have appeared in various London papers. Dover lodging-house keepers and their agents persist in thinking that the meeting of the Association will permit Ascot week charges to be made. There are lodgings of all kinds to be found at really moderate charges without difficulty, and the local secretaries are willing to do all in their power to assist members to obtain such accommodation. The strongest representations have been made to the agents on the subject, and it is probable that there will be no further difficulties; but of course it is hard to remove an impression which has got abroad.

The installation of the Marconi system of wireless telegraphy has now been made in the Town Hall, and a sufficiently lofty pole has been erected to permit of the direct transmission of messages to Wimereux. It is intended that Prof. Fleming should transmit a message of congratulation on the evening of his lecture to the meeting held at Rome on the same day, and that the reply will reach Boulogne by the ordinary wire, and be transmitted by the wireless system before the meeting terminates. Demonstrations of the Marconi system of telegraphy will take place at the Mayor's conversazione on Thursday evening.

It is hoped that about 400 of the French men of science will attend the luncheon to members of the French Association on Saturday. Some twenty Belgian geologists, who have been visiting London during the past ten days, will also be present.

On the occasion of the French visit there will be special facilities for the inspection of the Castle, which will be closed to the general public on the afternoon of Saturday, to permit the military authorities to devote themselves entirely to the members of the British Association and their guests.

The details of the foreign tour are all settled. Those who take part in this tour will have every occasion to look back with pleasure upon a very pleasant visit. At most of the towns visited there will be official receptions, with something of a special nature at Brussels on Sunday, September 24.

The following details of the work in the Sections, omitted from last week's article, have now been supplied.

In Section C (Geology) the address of the President, Sir Archibald Geikie, will, it is hoped, be delivered on Saturday, September 16, in order that the members of the French Association may be present. The address will deal with matters of equal interest to geologists and physicists. Reports will be presented by a committee appointed at the Toronto meeting to investigate the Pleistocene flora and fauna of Canada; by a committee which has been securing photographic records of the disappearing drift section at Moel Tryfan; by the three committees appointed a short time ago to investigate the ossiferous caves at Uphill, near Weston-super-Mare, the Ty-Newydd caves, and the Irish elk remains in the Isle of Man. The report of the committee which has been engaged for some years in collecting photographs of geological interest in the British Isles, will this year be accompanied by that of a similar committee appointed for the same purpose in Canada; and reports may be expected from other committees on erratic blocks, on life-zones in British carboniferous rocks, and on the registration of type specimens.

The chief interest of this Section will, no doubt, centre round the explorations for coal in Kent, and communications on this subject from Prof. Boyd Dawkins and Mr. Robert Etheridge will be awaited with expectation: in connection with this subject Mr. Jukes-Browne promises a paper on a boring made through the chalk at Dieppe in 1898. Many French and Belgian geologists will, it is hoped, take part in the discussion on this and kindred subjects, especially as the Belgian Geological Society is holding a special meeting at Dover during that of the British Association. Among foreign visitors Prof. van den Broeck promises a paper on the Iguanodons of Bernissart, and Prof. Renard one on the origin of chondritic meteorites.

Among papers of local interest will be one by Prof. Boyd Dawkins on the geology of the Channel Tunnel; one by Dr. Rowe on the Dover chalk; and one by Captain McDakin on coast erosion. Among other papers promised in this Section may be mentioned Prof. Sollas on homotaxy and on contemporaneity, and also on the origin of flint; Mr. Vaughan Cornish on photographs of wave phenomena; Dr. F. Moreno on Neomylodon; Prof. Watts on the Mount Sorel granite; Mr. G. Abbott on water zones and their influence on concretions; Mr. Plunkett on the Fermanagh Caves; and Dr. Tempest Anderson on the 1898 eruption of Vesuvius.

In Section G (Mechanical Science) the programme of papers to be read and discussed is as follows:—Thursday, Presidential Address by Sir William White, K.C.B., F.R.S.; the Dover Admiralty Harbour Works, by W. Mathews; non-inflammable wood and its use in warships, by E. Marshall Fox. Friday, a short history of the engineering works of the Suez Canal to the present time, by Sir Charles Hartley, K.C.M.G; fast cross-Channel steamers, by Hon. C. A. Parsons, F.R.S.; the Niclausse water-tube boiler, by M. Robinson; the discharge of torpedoes below water, by Captain Lloyd. Saturday, the erection of Alexander III. Bridge in Paris, by A. Alby (of Paris). Monday, electrical machinery on board ship, by A. Siemens; earth currents from electric tramways, by J. Swinburne; some recent applications of electrometallurgy to chemical engineering, by Sherard Cowper Coles; signalling without contact, a new system of railway signalling, by Wilfrid S. Boult. Tuesday, recent experiences with steam on common roads, by J. I. Thornycroft, F.R.S.; the Dymchurch wall and the reclamation of Romney Marsh, by E. Case; an instrument for gauging the circularity of boiler furnaces and producing a diagram, by T. Messenger; and the sea lights of the south and south-east coasts of England, including the Channel and Scilly Islands, by T. Kenward.

INAUGURAL ADDRESS BY PROF. SIR MICHAEL FOSTER, K.C.B., SEC.R.S., PRESIDENT OF THE ASSOCIATION.

HE who until a few minutes ago was your President said somewhere at the meeting at Bristol, and said with truth, that among the qualifications needed for the high honour of Presidency of the British Association for the Advancement of Science, that of being old was becoming more and more dominant. He who is now attempting to speak to you feels that he is rapidly earning that distinction. But the Association itself is older than its President; it has seen pass away the men who, wise in their generation, met at York on September 27, 1831, to found it: it has seen other great men who in bygone years served it as Presidents, or otherwise helped it on, sink one after another into the grave. Each year, indeed, when it plants its flag as a signal of its yearly meeting, that flag floats half-mast high in token of the great losses which the passing year has brought. This year is no exception; the losses, indeed, are perhaps unwontedly heavy. I will not attempt to call over the sad roll-call; but I must say a word about one who was above most others a faithful and zealous friend of the Association. Sir Douglas Galton joined the Association in 1860. From 1871 to 1895, as one of the General Secretaries, he bore, and bore to the great good of the Association, a large share of the burden of the Association's work. How great that share was is perhaps especially known to the many men, among whom I am proud to count myself, who during his long term of office served in succession with him as brother General Secretary. In 1895, at Ipswich, he left the post of General Secretary, but only to become President. So long and so constantly did he labour for the good of the Association that he seemed to be an integral part of it, and meeting as we do to-day, and as we henceforward must do, without Douglas Galton, we feel something greatly missing. This year, perhaps even more than in other years, we could have wished him to be among us; for to-day the Association may look with joy, not unmixed with pride, on the realisation of a project in forwarding which it has had a conspicuous share, on the commencement of an undertaking which is not only a great thing in itself, but which, we trust, is the beginning of still greater things to come. And the share which the Association has had in this was largely Sir Douglas Galton's doing. In his Address as President of Section A, at the meeting of the Association at Cardiff in 1891, Prof. Oliver Lodge expounded with pregnant words how urgently, not pure science only, but industry and the constructive arts—for the interests of these are ever at bottom the same—needed the aid of some national establishment for the prosecution of prolonged and costly physical researches, which private enterprise could carry out in a lame fashion only, if at all. Lodge's words found an echo in many men's minds; but the response was for a long while in men's minds only. In 1895 Sir Douglas Galton, having previously made a personal study of an institution analogous to the one desired—namely, the Reichsanstalt at Berlin—seized the opportunity offered to him as President of the Association at Ipswich to insist, with the authority not only of the head for the time being of a great scientific body, but also of one who himself knew the ways and wants at once of science and of practical life, that the thing which Lodge and others had hoped for was a thing which could be done, and ought to be done at once. And now to-day we can say it has been done. The National Physical Laboratory has been founded. The Address at Ipswich marked the beginning of an organised effort which has at last been crowned with success. A feeling of sadness cannot but come over us when we think that Sir Douglas Galton was not spared to see the formal completion of the scheme whose birth he did so much to help, and which, to his last days, he aided in more ways than one. It is the old story—the good which men do lives after them.

Still older than the Association is this nineteenth century, now swiftly drawing to its close. Though the century itself has yet some sixteen months to run, this is the last meeting of the British Association which will use the numbers eighteen hundred to mark its date.

The eyes of the young look ever forward; they take little heed of the short though ever-lengthening fragment of life which lies behind them; they are wholly bent on that which is to come. The eyes of the aged turn wistfully again and again to the past; as the old glide down the inevitable slope their present becomes a living over again the life which has gone before, and the future takes on the shape of a brief lengthening of the past. May I this evening venture to give rein to the impulses of advancing years? May I, at this last meeting of the Association in the eighteen hundreds, dare to dwell for a while upon the past, and to call to mind a few of the changes which have taken place in the world since those autumn days in which men were saying to each other that the last of the seventeen hundreds was drawing towards its end?

Dover in the year of our Lord seventeen hundred and ninety-nine was in many ways unlike the Dover of to-day. On moonless nights men groped their way in its narrow streets by the help of swinging lanterns and smoky torches, for no lamps lit the ways. By day the light of the sun struggled into the houses through narrow panes of blurred glass. Though the town then, as now, was one of the chief portals to and from the countries beyond the seas, the means of travel were scanty and dear, available for the most part to the rich alone, and, for all, beset with discomfort and risk. Slow and uncertain was the carriage of goods, and the news of the world outside came to the town—though it from its position learnt more than most towns—tardily, fitfully, and often falsely. The people of Dover sat then much in dimness, if not in darkness, and lived in large measure on themselves. They who study the phenomena of living beings tell us that light is the great stimulus of life and that the fulness of the life of a being or of any of its members may be measured by the variety, the swiftness, and the certainty of the means by which it is in touch with its surroundings. Judged from this standpoint then life at Dover, as indeed elsewhere, must have fallen far short of the life of to-day.

The same study of living beings, however, teaches us that while from one point of view the environment seems to mould the organism, from another point the organism seems to be master of its environment. Going behind the change of circumstances, we may raise the question, the old question, Was life in its essence worth more then than now? Has there been a real advance?

Let me at once relieve your minds by saying that I propose to leave this question in the main unanswered. It may be, or it may not be, that man's grasp of the beautiful and of the good, if not looser, is not firmer than it was a hundred years ago. It may be, or it may not be, that man is no nearer to absolute truth, to seeing things as they really are, than he was then. I will merely ask you to consider with me for a few minutes how far, and in what ways, man's laying hold of that aspect of or part of truth which we call natural knowledge, or sometimes science, differed in 1799 from what it is to-day, and whether that change must not be accounted a real advance, a real improvement in man.

I do not propose to weary you by what in my hands would be the rash effort of attempting a survey of all the scientific results of the nineteenth century. It will be enough if for a little while I dwell on some few of the salient features distinguishing the way in which we nowadays look upon, and during the coming week shall speak of, the works of nature around us—though those works themselves, save for the slight shifting involved in a secular change, remain exactly the same—from the way in which they were looked upon and might have been spoken of at a gathering of philosophers at Dover in 1799. And I ask your leave to do so.

In the philosophy of the ancients, earth, fire, air, and water were called "the elements." It was thought, and rightly thought, that a knowledge of them and of their attributes was a necessary basis of a knowledge of the ways of nature. Translated into modern language, a knowledge of these "elements" of old means a knowledge of the composition of the atmosphere, of water, and of all the other things which we call matter, as well as a knowledge of the general properties of gases, liquids, and solids, and of the nature and effects of combustion. Of all these things our knowledge to-day is large and exact, and, though ever enlarging, in some respects complete. When did that knowledge begin to become exact?

To-day the children in our schools know that the air which wraps round the globe is not a single thing, but is made up of two things, oxygen and nitrogen,[1] mingled together. They know, again, that water is not a single thing, but the product of two things, oxygen and hydrogen, joined together. They know that when the air makes the fire burn and gives the animal life, it is the oxygen in it which does the work. They know that all

[1] Some may already know that there is at least a third thing, argon.

round them things are undergoing that union with oxygen which we call oxidation, and that oxidation is the ordinary source of heat and light. Let me ask you to picture to yourselves what confusion there would be to-morrow, not only in the discussions at the sectional meetings of our Association, but in the world at large, if it should happen that in the coming night some destroying touch should wither up certain tender structures in all our brains, and wipe out from our memories all traces of the ideas which cluster in our minds around the verbal tokens, oxygen and oxidation. How could any of us, not the so-called man of science alone, but even the man of business and the man of pleasure, go about his ways lacking those ideas? Yet those ideas were in 1799 lacking to all but a few.

Although in the third quarter of the seventeenth century the light of truth about oxidation and combustion had flashed out in the writings of John Mayow, it came as a flash only, and died away as soon as it had come. For the rest of that century, and for the greater part of the next, philosophers stumbled about in darkness, misled for the most of the time by the phantom conception which they called phlogiston. It was not until the end of the third quarter of the eighteenth century that the new light, which has burned steadily ever since, lit up the minds of the men of science. The light came at nearly the same time from England and from France. Rounding off the sharp corners of controversy, and joining, as we may fitly do to-day, the two countries as twin bearers of a common crown, we may say that we owe the truth to Priestley, to Lavoisier, and Cavendish. If it was Priestley who was the first to demonstrate the existence of what we now call oxygen, it is to Lavoisier we owe the true conception of the nature of oxidation and the clear exposition of the full meaning of Priestley's discovery, while the knowledge of the composition of water, the necessary complement of the knowledge of oxygen, came to us through Cavendish and, we may perhaps add, through Watt.

The date of Priestley's discovery of oxygen is 1774, Lavoisier's classic memoir "on the nature of the principle which enters into combination with metals during calcination" appeared in 1775, and Cavendish's paper on the composition of water did not see the light until 1784.

During the last quarter of the eighteenth century this new idea of oxygen and oxidation was struggling into existence. How new was the idea is illustrated by the fact that Lavoisier himself at first spoke of that which he was afterwards, namely in 1778, led to call oxygen, the name by which it has since been known, as "the principle which enters into combination." What difficulties its acceptance met with is illustrated by the fact that Priestley himself refused to the end of his life to grasp the true bearings of the discovery which he had made. In the year 1799 the knowledge of oxygen, of the nature of water and of air, and indeed the true conception of chemical composition and chemical change, was hardly more than beginning to be, and the century had to pass wholly away before the next great chemical idea, which we know by the name of the Atomic Theory of John Dalton, was made known. We have only to read the scientific literature of the time to recognise that a truth which is now not only woven as a master-thread into all our scientific conceptions, but even enters largely into the everyday talk and thoughts of educated people, was a hundred years ago struggling into existence among the philosophers themselves. It was all but absolutely unknown to the large world outside those select few.

If there be one word of science which is writ large on the life of the present time, it is the word "electricity"; it is, I take it, writ larger than any other word. The knowledge which it denotes has carried its practical results far and wide into our daily life, while the theoretical conceptions which it signifies pierce deep into the nature of things. We are to-day proud, and justly proud, both of the material triumphs and of the intellectual gains which it has brought us, and we are full of even larger hopes of it in the future.

At what time did this bright child of the nineteenth century have its birth?

He who listened to the small group of philosophers of Dover, who in 1799 might have discoursed of natural knowledge, would perhaps have heard much of electric machines, of electric sparks, of the electric fluid, and even of positive and negative electricity; for frictional electricity had long been known and even carefully studied. Probably one or more of the group, dwelling on the observations which Galvani, an Italian, had made known some twenty years before, developed views on the connection of electricity with the phenomena of living bodies. Possibly one of them was exciting the rest by telling how he had just heard that a professor at Pavia, one Volta, had discovered that electricity could be produced not only by rubbing together particular bodies, but by the simple contact of two metals, and had thereby explained Galvani's remarkable results. For, indeed, as we shall hear from Prof. Fleming, it was in that very year, 1799, that electricity as we now know it took its birth. It was then that Volta brought to light the apparently simple truths out of which so much has sprung. The world, it is true, had to wait for yet some twenty years before both the practical and the theoretic worth of Volta's discovery became truly pregnant, under the fertilising influence of another discovery. The loadstone and magnetic virtues had, like the electrifying power of rubbed amber, long been an old story. But, save for the compass, not much had come from it. And even Volta's discovery might have long remained relatively barren had it been left to itself. When, however, in 1819, Oersted made known his remarkable observations on the relations of electricity to magnetism, he made the contact needed for the flow of a new current of ideas. And it is perhaps not too much to say that those ideas, developing during the years of the rest of the century with an ever-accelerating swiftness, have wholly changed man's material relations to the circumstances of life, and at the same time carried him far in his knowledge of the nature of things.

Of all the various branches of science, none perhaps is to-day, none for these many years past has been, so well known to, even if not understanded by, most people as that of geology. Its practical lessons have brought wealth to many; its fairy tales have brought delight to more; and round it hovers the charm of danger, for the conclusions to which it leads touch on the nature of man's beginning.

In 1799 the science of geology, as we know it, was struggling into birth. There had been from of old cosmogonies, theories as to how the world had taken shape out of primæval chaos. In that fresh spirit which marked the zealous search after natural knowledge pursued in the middle and latter part of the seventeenth century, the brilliant Stenson, in Italy, and Hooke, in our own country, had laid hold of some of the problems presented by fossil remains; and Woodward, with others, had laboured in the same field. In the eighteenth century, especially in its latter half, men's minds were busy about the physical agencies determining or modifying the features of the earth's crust; water and fire, subsidence from a primæval ocean and transformation by outbursts of the central heat, Neptune and Pluto, were being appealed to, by Werner on the one hand, and by Desmarest on the other, in explanation of the earth's phenomena. The way was being prepared, theories and views were abundant, and many sound observations had been made; and yet the science of geology, properly so called, the exact and proved knowledge of the successive phases of the world's life, may be said to date from the closing years of the eighteenth century.

In 1873 James Hutton put forward in a brief memoir his "Theory of the Earth," which in 1795, two years before his death, he expanded into a book; but his ideas failed to lay hold of men's minds until the century had passed away, when in 1802 they found an able expositor in John Playfair. The very same year that Hutton published his theory, Cuvier came to Paris and almost forthwith began, with Brongniart, his immortal researches into the fossils of Paris and its neighbourhood. And four years later, in the year 1799 itself, William Smith's tabular list of strata and fossils saw the light. It is, I believe, not too much to say that out of these geology, as we now know it, sprang. It was thus in the closing years of the eighteenth century that was begun the work which the nineteenth century has carried forward to such great results. But at that time only the select few had grasped the truth, and even they only the beginning of it. Outside a narrow circle the thoughts, even of the educated, about the history of the globe were bounded by the story of the Delnge—though the story was often told in a strange fashion—or were guided by fantastic views of the plastic forces of a sportive nature.

In another branch of science, in that which deals with the problems presented by living beings, the thoughts of men in 1799 were also very different from the thoughts of men to-day.

It is a very old quest, the quest after the knowledge of the nature of living beings, one of the earliest on which man set out; for it promised to lead him to a knowledge of himself, a promise which perhaps is still before us, but the fulfilment of which is as yet far off. As time has gone on, the pursuit of natural knowledge has seemed to lead man away from himself into the furthermost parts of the universe, and into secret workings of nature in which he appears to be of little or no account; and his knowledge of the nature of living things, and so of his own nature, has advanced slowly, waiting till the progress of other branches of natural knowledge can bring it aid. Yet in the past hundred years, the biologic sciences, as we now call them, have marched rapidly onward.

We may look upon a living body as a machine doing work in accordance with certain laws, and may seek to trace out the working of the inner wheels, how these raise up the lifeless dust into living matter, and let the living matter fall away again into dust, giving out movement and heat. Or we may look upon the individual life as a link in a long chain, joining something which went before to something about to come, a chain whose beginning lies hid in the farthest past, and may seek to know the ties which bind one life to another. As we call up to view the long series of living forms, living now or flitting like shadows on the screen of the past, we may strive to lay hold of the influences which fashion the garment of life. Whether the problems of life are looked upon from the one point of view or the other, we to-day, not biologists only, but all of us, have gained a knowledge hidden even from the philosophers a hundred years ago.

Of the problems presented by the living body viewed as a machine, some may be spoken of as mechanical, others as physical, and yet others as chemical. while some are, apparently at least, none of these. In the seventeenth century William Harvey, laying hold of the central mechanism of the blood stream, opened up a path of inquiry which his own age and the century which followed trod with marked success. The knowledge of the mechanics of the animal and of the plant advanced apace; but the physical and chemical problems had yet to wait. The eighteenth century, it is true, had its physics and its chemistry; but, in relation at least to the problems of the living being, a chemistry which knew not oxygen and a physics which knew not the electricity of chemical action were of little avail. The philosopher of 1799, when he discussed the functions of the animal or of the plant involving chemical changes, was fain for the most part, as were his predecessors in the century before, to have recourse to such vague terms as "fermentation" and the like; to-day our treatises on physiology are largely made up of precise and exact expositions of the play of physical agencies and chemical bodies in the living organism. He made use of the words "vital force" or "vital principle," not as an occasional, but as a common explanation of the phenomena of the living body. During the present century, especially during its latter half, the idea embodied in those words has been driven away from one seat after another; if we use it now when we are dealing with the chemical and physical events of life we use it with reluctance, as a *deus ex machina* to be appealed to only when everything else has failed.

Some of the problems—and those, perhaps, the chief problems—of the living body have to be solved neither by physical nor by chemical methods, but by methods of their own. Such are the problems of the nervous system. In respect to these the men of 1799 were on the threshold of a pregnant discovery. During the latter part of the present century, and especially during its last quarter, the analysis of the mysterious processes in the nervous system which issue as feeling, thought, and power to move, has been pushed forward with a success conspicuous in its practical, and full of promise in its theoretical, gains. That analysis may be briefly described as a following up of threads. We now know that what takes place along a tiny thread which we call a nerve-fibre differs from that which takes place along its fellow-threads, that differing nervous impulses travel along different nerve-fibres, and that nervous and psychical events are the outcome of the clashing of nervous impulses as they sweep along the closely-woven web of living threads of which the brain is made. We have learnt by experiment and by observation that the pattern of the web determines the play of the impulses, and we can already explain many of the obscure problems, not only of nervous disease, but of nervous life, by an analysis which is a tracking out the devious and linked paths of nervous threads. The very beginning of this analysis was known in 1799. Men knew that nerves were the agents of feeling and of the movements of muscles; they had learnt much about what this part or that part of the brain could do; but they did not know that one nerve-fibre differed from another in the very essence of its work. It was just about the end of the past century, or the beginning of the present one, that an English surgeon began to ponder over a conception which, however, he did not make known until some years later, and which did not gain complete demonstration and full acceptance until still more years had passed away. It was in 1811, in a tiny pamphlet published privately, that Charles Bell put forward his "New Idea" that the nervous system was constructed on the principle that "the nerves are not single nerves possessing various powers, but bundles of different nerves, whose filaments are united for the convenience of distribution, but which are distinct in office as they are in origin from the brain."

Our present knowledge of the nervous system is to a large extent only an exemplification and expansion of Charles Bell's "New Idea," and has its origin in that.

If we pass from the problems of the living organism viewed as a machine to those presented by the varied features of the different creatures who have lived or who still live on the earth, we at once call to mind that the middle years of the present century mark an epoch in biologic thought such as never came before, for it was then that Charles Darwin gave to the world the "Origin of Species."

That work, however, with all the far-reaching effects which it has had, could have had little or no effect, or, rather, could not have come into existence, had not the earlier half of the century been in travail preparing for its coming. For the germinal idea of Darwin appeals, as to witnesses, to the results of two lines of biologic investigation which were almost unknown to the men of the eighteenth century.

To one of these lines I have already referred. Darwin, as we know, appealed to the geological record: and we also know how that record, imperfect as it was then, and imperfect as it must always remain, has since his time yielded the most striking proofs of at least one part of his general conception. In 1799 there was, as we have seen, no geological record at all.

Of the other line I must say a few words.

To-day the merest beginner in biologic study, or even that exemplar of acquaintance without knowledge, the general reader, is aware that every living being, even man himself, begins its independent existence as a tiny ball, of which we can, even acknowledging to the full the limits of the optical analysis at our command, assert with confidence that in structure, using that word in its ordinary sense, it is in all cases absolutely simple. It is equally well known that the features of form which supply the characters of a grown-up living being, all the many and varied features of even the most complex organism, are reached as the goal of a road, at times a long road, of successive changes; that the life of every being, from the ovum to its full estate, is a series of shifting scenes, which come and go, sometimes changing abruptly, sometimes melting the one into the other, like dissolving views, all so ordained that often the final shape with which the creature seems to begin, or is said to begin, its life in the world is the outcome of many shapes, clothed with which it has in turn lived many lives before its seeming birth.

All or nearly all the exact knowledge of the laboured way in which each living creature puts on its proper shape and structure is the heritage of the present century. Although the way in which the chick is moulded in the egg was not wholly unknown even to the ancients, and in later years had been told, first in the sixteenth century by Fabricius, then in the seventeenth century in a more clear and striking manner by the great Italian naturalist Malpighi, the teaching thus offered had been neglected or misinterpreted. At the close of the eighteenth century the dominant view was that in the making of a creature out of the egg there was no putting on of wholly new parts, no epigenesis. It was taught that the entire creature lay hidden in the egg, hidden by reason of the very transparency of its substance, lay ready-made but folded up, as it were, and that the process of development within the egg or within the womb was a mere unfolding, a simple evolution. Nor did men shrink from accepting the logical outcome of such a view—namely, that within the unborn creature itself lay in like manner, hidden and folded up, its offspring also, and within that again its offspring in turn, after the fashion of a cluster of

ivory balls carved by Chinese hands, one within the other. This was no fantastic view put forward by an imaginative dreamer; it was seriously held by sober men, even by men like the illustrious Haller, in spite of their recognising that as the chick grew in the egg some changes of form took place. Though so early as the middle of the eighteenth century Friedrich Caspar Wolff and, later on, others had strenuously opposed such a view, it held its own, not only to the close of the century, but far on into the next. It was not until a quarter of the present century had been added to the past that Von Baer made known the results of researches which once and for all swept away the old view. He and others working after him made it clear that each individual puts on its final form and structure, not by an unfolding of pre-existing hidden features, but by the formation of new parts through the continued differentiation of a primitively simple material. It was also made clear that the successive changes which the embryo undergoes in its progress from the ovum to maturity are the expression of morphologic laws, that the progress is one from the general to the special, and that the shifting scenes of embryonic life are hints and tokens of lives lived by ancestors in times long past.

If we wish to measure how far off in biologic thought the end of the last century stands, not only from the end but even from the middle of this one, we may imagine Darwin striving to write the "Origin of Species" in 1799. We may fancy him being told by philosophers that one group of living beings differed from another group because all its members and all their ancestors came into existence at one stroke when the firstborn progenitor of the race, within which all the rest were folded up, stood forth as the result of a creative act. We may fancy him listening to a debate between the philosopher who maintained that all the fossils strewn in the earth were the remains of animals or plants churned up in the turmoil of a violent universal flood, and dropped in their places as the waters went away, and him who argued that such were not really the "spoils of living creatures," but the products of some playful plastic power which out of the superabundance of its energy fashioned here and there the lifeless earth into forms which imitated, but only imitated, those of living things. Could he amid such surroundings by any flight of genius have beat his way to the conception for which his name will ever be known?

Here I may well turn away from the past. It is not my purpose, nor, as I have said, am I fitted, nor is this perhaps the place, to tell even in outline the tale of the work of science in the nineteenth century. I am content to have pointed out that the two great sciences of chemistry and geology took their birth, or at least began to stand alone, at the close of the last century, and have grown to be what we know them now within about a hundred years, and that the study of living beings has within the same time been so transformed as to be to-day something wholly different from what it was in 1799. And, indeed, to say more would be to repeat almost the same story about other things. If our present knowledge of electricity is essentially the child of the nineteenth century, so also is our present knowledge of many other branches of physics. And those most ancient forms of exact knowledge, the knowledge of numbers and of the heavens, whose beginning is lost in the remote past, have, with all other kinds of natural knowledge, moved onward during the whole of the hundred years with a speed which is ever increasing. I have said, I trust, enough to justify the statement that in respect to natural knowledge a great gulf lies between 1799 and 1899. That gulf, moreover, is a twofold one: not only has natural knowledge been increased, but men have run to and fro spreading it as they go. Not only have the few driven far back round the full circle of natural knowledge the dark clouds of the unknown which wrap us all about, but also the many walk in the zone of light thus increasingly gained. If it be true that the few to-day are, in respect to natural knowledge, far removed from the few of those days, it is also true that nearly all which the few alone knew then, and much which they did not know, has now become the common knowledge of the many.

What, however, I may venture to insist upon here is that the difference in respect to natural knowledge, whatever be the case with other differences between then and now, is undoubtedly a difference which means progress. The span between the science of that time and the science of to-day is beyond all question a great stride onwards.

We may say this, but we must say it without boasting. For the very story of the past which tells of the triumphs of science bids the man of science put away from him all thoughts of vain-glory. And that by many tokens.

Whoever, working at any scientific problem, has occasion to study the inquiries into the same problem made by some fellow-worker in the years long gone by, comes away from that study humbled by one or other of two different thoughts. On the one hand, he may find, when he has translated the language of the past into the phraseology of to-day, how near was his forerunner of old to the conception which he thought, with pride, was all his own, not only so true but so new. On the other hand, if the ideas of the investigator of old, viewed in the light of modern knowledge, are found to be so wide of the mark as to seem absurd, the smile which begins to play upon the lips of the modern is checked by the thought, Will the ideas which I am now putting forth, and which I think explain so clearly, so fully, the problem in hand, seem to some worker in the far future as wrong and as fantastic as do these of my forerunner to me? In either case his personal pride is checked. Further, there is written clearly on each page of the history of science, in characters which cannot be overlooked, the lesson that no scientific truth is born anew, coming by itself and of itself. Each new truth is always the offspring of something which has gone before, becoming in turn the parent of something coming after. In this aspect the man of science is unlike, or seems to be unlike, the poet and the artist. The poet is born, not made; he rises up, no man knowing his beginnings; when he goes away, though men after him may sing his songs for centuries, he himself goes away wholly, having taken with him his mantle, for this he can give to none other. The man of science is not thus creative; he is created. His work, however great it be, is not wholly his own; it is in part the outcome of the work of men who have gone before. Again and again a conception which has made a name great has come, not so much by the man's own effort as out of the fulness of time. Again and again we may read in the words of some man of old the outlines of an idea which in later days has shone forth as a great acknowledged truth. From the mouth of the man of old the idea dropped barren, fruitless: the world was not ready for it, and heeded it not; the concomitants and abutting truths which could give it power to work were wanting. Coming back again in later days, the same idea found the world awaiting it; things were in travail preparing for it; and some one, seizing the right moment to put it forth again, leapt into fame. It is not so much the men of science who make science, as some spirit which, born of the truths already won, drives the man of science onward, and uses him to win new truths in turn.

It is because each man of science is not his own master, but one of many obedient servants of an impulse which was at work long before him, and will work long after him, that in science there is no falling back. In respect to other things there may be times of darkness and times of light, there may be risings, decadences, and revivals. In science there is only progress. The path may not be always a straight line, there may be swerving to this side and to that, ideas may seem to return again and again to the same point of the intellectual compass; but it will always be found that they have reached a higher level—they have moved, not in a circle, but in a spiral. Moreover, science is not fashioned as is a house, by putting brick to brick, that which is once put remaining as it was put to the end. The growth of science is that of a living being. As in the embryo phase follows phase, and each member of the body puts on in succession different appearances, though all the while the same member, so a scientific conception of one age seems to differ from that of a following age, though it is the same one in the process of being made; and as the dim outlines of the early embryo, as the being grows, become more distinct and sharp, like a picture on a screen brought more and more into focus, so the dim gropings and searchings of the men of science of old are by repeated approximations wrought into the clear and exact conclusions of later times.

The story of natural knowledge, of science, in the nineteenth century, as, indeed, in preceding centuries, is, I repeat, a story of continued progress. There is in it not so much as a hint of falling back, not even of standing still. What is gained by scientific inquiry is gained for ever; it may be added to, it may seem to be covered up, but it can never be taken away. Confident that the progress will go on, we cannot help peering

into the years to come and straining our eyes to foresee what science will become and what it will do as they roll on. While we do so, the thought must come to us, Will all the increasing knowledge of nature avail only to change the ways of man—will it have no effect on man himself?

The material good which mankind has gained and is gaining through the advance of science is so imposing as to be obvious to every one, and the praises of this aspect of science are to be found in the mouths of all. Beyond all doubt science has greatly lessened and has markedly narrowed hardship and suffering; beyond all doubt science has largely increased and has widely diffused ease and comfort. The appliances of science have, as it were, covered with a soft cushion the rough places of life, and that not for the rich only, but also for the poor. So abundant and so prominent are the material benefits of science that in the eyes of many these seem to be the only benefits which she brings. She is often spoken of as if she were useful and nothing more, as if her work were only to administer to the material wants of man.

Is this so?

We may begin to doubt it when we reflect that the triumphs of science which bring these material advantages are in their very nature intellectual triumphs. The increasing benefits brought by science are the results of man's increasing mastery over nature, and that mastery is increasingly a mastery of mind; it is an increasing power to use the forces of what we call inanimate nature in place of the force of his own or other creatures' bodies; it is an increasing use of mind in place of muscle.

Is it to be thought that that which has brought the mind so greatly into play has had no effect on the mind itself? Is that part of the mind which works out scientific truths a mere slavish machine producing results it knows not how, having no part in the good which in its working it brings forth?

What are the qualities, the features of that scientific mind which has wrought, and is working, such great changes in man's relation to nature? In seeking an answer to this question we have not to inquire into the attributes of genius. Though much of the progress of science seems to take on the form of a series of great steps, each made by some great man, the distinction in science between the great discoverer and the humble worker is one of degree only, not of kind. As I was urging just now, the greatness of many great names in science is often, in large part, the greatness of occasion, not of absolute power. The qualities which guide one man to a small truth silently taking its place among its fellows, as these go to make up progress, are at bottom the same as those by which another man is led to something of which the whole world rings.

The features of the fruitful scientific mind are in the main three.

In the first place, above all other things, his nature must be one which vibrates in unison with that of which he is in search; the seeker after truth must himself be truthful, truthful with the truthfulness of nature. For the truthfulness of nature is not wholly the same as that which man sometimes calls truthfulness. It is far more imperious, far more exacting. Man, unscientific man, is often content with "the nearly" and "the almost." Nature never is. It is not her way to call the same two things which differ, though the difference may be measured by less than the thousandth of a milligramme or of a millimetre, or by any other like standard of minuteness. And the man who, carrying the ways of the world into the domain of science, thinks that he may treat nature's differences in any other way than she treats them herself, will find that she resents his conduct; if he in carelessness or in disdain overlooks the minute difference which she holds out to him as a signal to guide him in his search, the projecting tip, as it were, of some buried treasure, he is bound to go astray, and the more strenuously he struggles on, the farther will he find himself from his true goal.

In the second place, he must be alert of mind. Nature is ever making signs to us, she is ever whispering to us the beginnings of her secrets; the scientific man must be ever on the watch, ready at once to lay hold of nature's hint however small, to listen to her whisper however low.

In the third place, scientific inquiry, though it be pre-eminently an intellectual effort, has need of the moral quality of courage—not so much the courage which helps a man to face a sudden difficulty as the courage of steadfast endurance. Almost every inquiry, certainly every prolonged inquiry, sooner or later goes wrong. The path, at first so straight and clear, grows crooked and gets blocked; the hope and enthusiasm, or even the jaunty ease, with which the inquirer set out leave him, and he falls into a slough of despond. That is the critical moment calling for courage. Struggling through the slough he will find on the other side the wicket-gate opening up the real path; losing heart he will turn back and add one more stone to the great cairn of the unaccomplished.

But, I hear some one say, these qualities are not the peculiar attributes of the man of science; they may be recognised as belonging to almost every one who has commanded or deserved success, whatever may have been his walk of life. That is so. That is exactly what I would desire to insist, that the men of science have no peculiar virtues, no special powers. They are ordinary men, their characters are common, even commonplace. Science, as Huxley said, is organised common sense, and men of science are common men, drilled in the ways of common sense.

For their life has this feature. Though in themselves they are no stronger, no better than other men, they possess a strength which, as I just now urged, is not their own, but is that of the science whose servants they are. Even in his apprenticeship, the scientific inquirer, while learning what has been done before his time, if he learns it aright, so learns it that what is known may serve him, not only as a vantage ground whence to push off into the unknown, but also as a compass to guide him in his course. And when fitted for his work he enters on inquiry itself, what a zealous anxious guide, what a strict and, because strict, helpful schoolmistress does nature make herself to him! Under her care every inquiry, whether it bring the inquirer to a happy issue or seem to end in nought, trains him for the next effort. She so orders her ways that each act of obedience to her makes the next act easier for him, and step by step she leads him on towards that perfect obedience which is complete mastery.

Indeed, when we reflect on the potency of the discipline of scientific inquiry we cease to wonder at the progress of scientific knowledge. The results actually gained seem to fall so far short of what under such guidance might have been expected to have been gathered in that we are fain to conclude that science has called to follow her, for the most part, the poor in intellect and the wayward in spirit. Had she called to her service the many acute minds who have wasted their strength struggling in vain to solve hopeless problems, or who have turned their energies to things other than the increase of knowledge; had she called to her service the many just men who have walked straight without the need of a rod to guide them, how much greater than it has been would have been the progress of science, and how many false teachings would the world have been spared! To men of science themselves, when they consider their favoured lot, the achievements of the past should serve, not as a boast, but as a reproach.

If there be any truth in what I have been urging, that the pursuit of scientific inquiry is itself a training of special potency, giving strength to the feeble and keeping in the path those who are inclined to stray, it is obvious that the material gains of science, great as they may be, do not make up all the good which science brings or may bring to man. We especially, perhaps, in these later days, through the rapid development of the physical sciences, are too apt to dwell on the material gains alone. As a child in its infancy looks upon its mother only as a giver of good things, and does not learn till in after days how she was also showing her love by carefully training it in the way it should go, so we, too, have thought too much of the gifts of science, overlooking her power to guide.

Man does not live by bread alone, and science brings him more than bread. It is a great thing to make two blades of grass grow where before one alone grew; but it is no less great a thing to help a man to come to a just conclusion on the questions with which he has to deal. We may claim for science that while she is doing the one she may be so used as to do the other also. The dictum just quoted, that science is organised common sense, may be read as meaning that the common problems of life which common people have to solve are to be solved by the same methods by which the man of science solves his special problems. It follows that the training which does so much for him may be looked to as promising to do much for them. Such aid can come from science on two conditions

only. In the first place, this her influence must be acknowledged; she must be duly recognised as a teacher no less than as a hewer of wood and a drawer of water. And the pursuit of science must be followed, not by the professional few only, but, at least in such measure as will ensure the influence of example, by the many. But this latter point I need not urge before this great Association, whose chief object during more than half a century has been to bring within the fold of science all who would answer to the call. In the second place, it must be understood that the training to be looked for from science is the outcome, not of the accumulation of scientific knowledge, but of the practice of scientific inquiry. Man may have at his fingers' ends all the accomplished results and all the current opinions of any one or of all the branches of science, and yet remain wholly unscientific in mind; but no one can have carried out even the humblest research without the spirit of science in some measure resting upon him. And that spirit may in part be caught even without entering upon an actual investigation in search of a new truth. The learner may be led to old truths, even the oldest, in more ways than one. He may be brought abruptly to a truth in its finished form, coming straight to it like a thief climbing over the wall; and the hurry and press of modern life tempt many to adopt this quicker way. Or he may be more slowly guided along the path by which the truth was reached by him who first laid hold of it. It is by this latter way of learning the truth, and by this alone, that the learner may hope to catch something at least of the spirit of the scientific inquirer.

This is not the place, nor have I the wish, to plunge into the turmoil of controversy; but, if there be any truth in what I have been urging, then they are wrong who think that in the schooling of the young science can be used with profit only to train those for whom science will be the means of earning their bread. It may be that from the point of view of the pedagogic art the experience of generations has fashioned out of the older studies of literature an instrument of discipline of unusual power, and that the teaching of science is as yet but a rough tool in unpractised hands. That, however, is not an adequate reason why scope should not be given for science to show the value which we claim for it as an intellectual training fitted for all sorts and conditions of men. Nor need the studies of humanity and literature fear her presence in the schools, for if her friends maintain that that teaching is one-sided, and therefore misleading, which deals with the doings of man only, and is silent about the works of nature, in the sight of which he and his doings shrink almost to nothing, she herself would be the first to admit that that teaching is equally wrong which deals only with the works of nature and says nothing about the doings of man, who is, to us at least, nature's centre.

There is yet another general aspect of science on which I would crave leave to say a word. In that broad field of human life which we call politics, in the struggle, not of man with man, but of race with race, science works for good. If we look only on the surface it may at first sight seem otherwise. In no branch of science has there during these later years been greater activity and more rapid progress than in that which furnishes the means by which man brings death, suffering, and disaster on his fellow-men. If the healer can look with pride on the increased power which science has given him to alleviate human suffering and ward off the miseries of disease, the destroyer can look with still greater pride on the power which science has given him to sweep away lives and to work desolation and ruin; while the one has slowly been learning to save units, the other has quickly learnt to slay thousands. But, happily, the very greatness of the modern power of destruction is already becoming a bar to its use, and bids fair—may we hope before long?—wholly to put an end to it; in the words of Tacitus, though in another sense, the very preparations for war, through the character which science gives them, make for peace.

Moreover, not in one branch of science only, but in all, there is a deep undercurrent of influence sapping the very foundations of all war. As I have already urged, no feature of scientific inquiry is more marked than the dependence of each step forward on other steps which have been made before. The man of science cannot sit by himself in his own cave weaving out results by his own efforts, unaided by others, heedless of what others have done and are doing. He is but a bit of a great system, a joint in a great machine, and he can only work aright when he is in due touch with his fellow-workers. If his labour is to be what it ought to be, and is to have the weight which it ought to have, he must know what is being done, not by himself, but by others, and by others not of his own land and speaking his tongue only, but also of other lands and of other speech. Hence it comes about that to the man of science the barriers of manners and of speech which pen men into nations become more and more unreal and indistinct. He recognises his fellow-worker, wherever he may live and whatever tongue he may speak, as one who is pushing forward shoulder to shoulder with him towards a common goal, as one whom he is helping and who is helping him. The touch of science makes the whole world kin.

The history of the past gives us many examples of this brotherhood of science. In the revival of learning throughout the sixteenth and seventeenth centuries, and some way on into the eighteenth century, the common use of the Latin tongue made intercourse easy. In some respects, in those earlier days science was more cosmopolitan than it afterwards became. In spite of the difficulties and hardships of travel, the men of science of different lands again and again met each other face to face, heard with their ears, and saw with their eyes what their brethren had to say or to show. The Englishman took the long journey to Italy to study there; the Italian, the Frenchman, and the German wandered from one seat of learning to another; and many a man held a chair in a country not his own. There was help, too, as well as intercourse. The Royal Society of London took upon itself the task of publishing nearly all the works of the great Italian Malpighi, and the brilliant Lavoisier, two years before his own countrymen in their blind fury slew him, received from the same body the highest token which it could give of its esteem.

In these closing years of the nineteenth century this great need of mutual knowledge and of common action felt by men of science of different lands is being manifested in a special way. Though nowadays what is done anywhere is soon known everywhere, the news of a discovery being often flashed over the globe by telegraph, there is an increasing activity in the direction of organisation to promote international meetings and international co-operation. In almost every science inquirers from many lands now gather together at stated intervals in international congresses to discuss matters which they have in common at heart, and go away each one feeling strengthened by having met his brother. The desire that in the struggle to lay bare the secrets of Nature the least waste of human energy should be incurred is leading more and more to the concerted action of nations combining to attack problems the solution of which is difficult and costly. The determination of standards of measurement, magnetic surveys, the solution of great geodetic problems, the mapping of the heavens and of the earth—all these are being carried on by international organisations.

In this and in other countries men's minds have this long while past been greatly moved by the desire to make fresh efforts to pierce the dark secrets of the forbidding Antarctic regions. Belgium has just made a brave single-handed attempt; a private enterprise sailing from these shores is struggling there now, lost for the present to our view; and this year we in England and our brethren in Germany are, thanks to the promised aid of the respective Governments, and no less to private liberality, in which this Association takes its share, able to begin the preparation of carefully organised expeditions. That international amity of which I am speaking is illustrated by the fact that in this country and in that there is not only a great desire, but a firm purpose, to secure the fullest co-operation between the expeditions which will leave the two shores. If in this momentous attempt any rivalry be shown between the two nations, it will be for each a rivalry, not in forestalling, but in assisting the other. May I add that if the story of the past may seem to give our nation some claim to the seas as more peculiarly our own, that claim bespeaks a duty likewise peculiarly our own to leave no effort untried by which we may plumb the seas' yet unknown depths and trace their yet unknown shores? That claim, if it means anything, means that when nations are joining hands in the dangerous work of exploring the unknown South, the larger burden of the task should fall to Britain's share; it means that we in this country should see to it, and see to it at once, that the concerted Antarctic expedition, which in some two years or so will leave the shores of Germany, of England, and, perhaps, of other lands, should, so far as we are concerned, be so equipped and so sustained that the risk of failure and disaster may be made as small, and the

hope of being able, not merely to snatch a hurried glimpse of lands not yet seen, but to gather in with full hands a rich harvest of the facts which men not of one science only, but of many, long to know, as great as possible.

Another international scientific effort demands a word of notice. The need which every inquirer in science feels to know, and to know quickly, what his fellow-worker, wherever on the globe he may be carrying on his work or making known his results, has done or is doing, led some four years back to a proposal for carrying out by international co-operation a complete current index, issued promptly, of the scientific literature of the world. Though much labour in many lands has been spent upon the undertaking, the project is not yet an accomplished fact. Nor can this, perhaps, be wondered at, when the difficulties of the task are weighed. Difficulties of language, difficulties of driving in one team all the several sciences, which, like young horses, wish each to have its head free with leave to go its own way, difficulties mechanical and financial of press and post, difficulties raised by existing interests—these and yet other difficulties are obstacles not easy to be overcome. The most striking and the most encouraging features of the deliberations which have now been going on for three years have been the repeated expressions, coming not from this or that quarter only, but from almost all quarters, of an earnest desire that the effort should succeed, of a sincere belief in the good of international co-operation, and of a willingness to sink as far as possible individual interests for the sake of the common cause. In the face of such a spirit we may surely hope that the many difficulties will ultimately pass out of sight.

Perhaps, however, not the least notable fact of international co-operation in science is the proposal which has been made within the last two years that the leading academies of the world should, by representatives, meet at intervals to discuss questions in which the learned of all lands are interested. A month hence a preliminary meeting of this kind will be held at Wiesbaden; and it is at least probable that the closing year of that nineteenth century in which science has played so great a part may at Paris during the great World's Fair—which every friend, not of science only, but of humanity, trusts may not be put aside or even injured through any untoward event, and which promises to be an occasion, not of pleasurable sight-seeing only, but also, by its many international congresses, of international communing in the search for truth—witness the first select Witenagemote of the science of the world.

I make no apology for having thus touched on international co-operation. I should have been wanting, had I not done so, to the memorable occasion of this meeting. A hundred years ago two great nations were grappling with each other in a fierce struggle, which had lasted, with pauses, for many years, and was to last for many years to come; war was on every lip and in almost every heart. To-day this meeting has, by a common wish, been so arranged that those two nations should, in the persons of their men of science draw as near together as they can, with nothing but the narrow streak of the Channel between them, in order that they may take counsel together on matters in which they have one interest and a common hope. May we not look upon this brotherly meeting as one of many signs that science, though she works in a silent manner and in ways unseen by many, is steadily making for peace?

Looking back, then, in this last year of the eighteen hundreds, on the century which is drawing to its close, while we may see in the history of scientific inquiry much which, telling the man of science of his shortcomings and his weakness, bids him be humble, we see also much, perhaps more, which gives him hope. Hope is indeed one of the watchwords of science. In the latter-day writings of some who know not science, much may be read which shows that the writer is losing or has lost hope in the future of mankind. There are not a few of these; their repeated utterances make a sign of the times. Seeing in matters lying outside science few marks of progress and many tokens of decline or of decay, recognising in science its material benefits only, such men have thoughts of despair when they look forward to the times to come. But if there be any truth in what I have attempted to urge to-night, if the intellectual, if the moral influences of science are no less marked than her material benefits, if, moreover, that which she has done is but the earnest of that which she shall do, such men may pluck up courage and gather strength by laying hold of her garment. We men of science at least need not share their views or their fears. Our feet are set, not on the shifting sands of the opinions and of the fancies of the day, but on a solid foundation of verified truth, which by the labours of each succeeding age is made broader and more firm. To us the past is a thing to look back upon, not with regret, not as something which has been lost, never to be regained, but with content, as something whose influence is with us still, helping us on our further way. With us, indeed, the past points not to itself, but to the future; the golden age is in front of us, not behind us; that which we do know is a lamp whose brightest beams are shed into the unknown before us, showing us how much there is ahead and lighting up the way to reach it. We are confident in the advance because, as each one of us feels that any step forward which he may make is not ordered by himself alone and is not the result of his own sole efforts in the present, but is, and that in large measure, the outcome of the labours of others in the past, so each one of us has the sure and certain hope that as the past has helped him, so his efforts, be they great or be they small, will be a help to those to come.

## SECTION A.

### MATHEMATICS AND PHYSICS.

OPENING ADDRESS BY PROF. J. H. POYNTING, F.R.S., PRESIDENT OF THE SECTION.

THE members of this Section will, I am sure, desire me to give expression to the gratification that we all feel in the realisation of the scheme first proposed from this chair by Dr. Lodge, the scheme for the establishment of a National Physical Laboratory. It would be useless here to attempt to point out the importance of the step taken in the definite foundation of the Laboratory, for we all recognise that it was absolutely necessary for the due progress of physical research in this country. It is matter for congratulation that the initial guidance of the work of the Laboratory has been placed in such able hands.

While the investigation of nature is ever increasing our knowledge, and while each new discovery is a positive addition never again to be lost, the range of the investigation and the nature of the knowledge gained form the theme of endless discussion. And in this discussion, so different are the views of different schools of thought, that it might appear hopeless to look for general agreement, or to attempt to mark progress.

Nevertheless, I believe that in some directions there has been real progress, and that physicists, at least, are tending towards a general agreement as to the nature of the laws in which they embody their discoveries, of the explanations which they seek to give, and of the hypotheses they make in their search for explanations.

I propose to ask you to consider the terms of this agreement, and the form in which, as it appears to me, they should be drawn up.

The range of the physicist's study consists in the visible motions and other sensible changes of matter. The experiences with which he deals are the impressions on his senses, and his aim is to describe in the shortest possible way how his various senses have been, will be, or would be affected.

His method consists in finding out all likenesses, in classing together all similar events, and so giving an account as concise as possible of the motions and changes observed. His success in the search for likenesses and his striving after conciseness of description lead him to imagine such a constitution of things that likenesses exist even where they elude his observation, and he is thus enabled to simplify his classification on the assumption that the constitution thus imagined is a reality. He is enabled to predict on the assumption that the likenesses of the future will be the likenesses of the past.

His account of nature, then, is, as it is often termed, a descriptive account.

Were there no similarities in events, our account of them could not rise above a mere directory, with each individual event entered up separately with its address. But the similarities observed enable us to class large numbers of events together, to give general descriptions, and indeed to make, instead of a directory, a readable book of science, with laws as the headings of the chapters.

These laws are, I believe, in all cases brief descriptions of observed similarities. By way of illustration let us take two or three examples.

The law of gravitation states that to each portion of matter we can assign a constant—its mass—such that there is an acceleration towards it of other matter proportional to that mass divided by the square of its distance away. Or all bodies resemble each other in having this acceleration towards each other.

Hooke's law for the case of a stretched wire states that each successive equal small load produces an equal stretch, or states that the behaviour of the wire is similar for all equal small pulls.

Joule's law for the heat appearing when a current flows in a wire states that the rate of heat development is proportional to the square of the current multiplied by the resistance, or states that all the different cases resemble each other in having $H \div C^2Rt$ constant.

And, generally, when a law is expressed by an equation, that equation is a statement that two different sets of measurements are made, represented by the terms on the two sides of the equation, and that all the different cases resemble each other in that the two sets have the constant relation expressed by the equation. Accurate prediction is based on the assumption that when we have made the measurements on the one side of the equation we can tell the result of the measurements implied on the other side.

If this is a true account of the nature of physical laws, they have, we must confess, greatly fallen off in dignity. No long time ago they were quite commonly described as the Fixed Laws of Nature, and were supposed sufficient in themselves to govern the universe. Now we can only assign to them the humble rank of mere descriptions, often tentative, often erroneous, of similarities which we believe we have observed.

The old conception of laws as self-sufficing governors of nature was, no doubt, a survival of a much older conception of the scope of physical science, a mode of regarding physical phenomena which had itself passed away.

I imagine that originally man looked on himself and the result of his action in the motions and changes which he produced in matter, as the one type in terms of which he should seek to describe all motions and changes. Knowing that his purpose and will were followed by motions and changes in the matter about him, he thought of similar purpose and will behind all the motions and changes which he observed, however they occurred; and he believed, too, that it was necessary to think thus in giving any consistent account of his observations. Taking this anthropomorphic—or, shall we say, psychical—view, the laws he formulated were not merely descriptions of similarities of behaviour, but they were also expressions of fixed purpose and the resulting constancy of action. They were commands given to matter which it must obey.

The psychical method, the introduction of purpose and will, is still appropriate when we are concerned with living beings. Indeed, it is the only method which we attempt to follow when we are describing the motions of our fellow-creatures. No one seeks to describe the motions and actions of himself and of his fellow-men, and to classify them without any reference to the similarity of purpose when the actions are similar. But as the study of nature progressed, it was found to be quite futile to bring in the ideas of purpose and will when merely describing and classifying the motions and changes of non-living matter. Purpose and will could be entirely left out of sight, and yet the observed motions and changes could be described, and predictions could be made as to future motions and changes. Limiting the aim of physical science to such description and prediction, it gradually became clear that the method was adequate for the purpose, and over the range of non-living matter, at least, the psychical yielded to the physical. Laws ceased to be commands analogous to legal enactments, and became mere descriptions. But during the passage from one position to the other, by a confusion of thought which may appear strange to us now that we have finished the journey, though no doubt it was inevitable, the purpose and will of which the laws had been the expression were put into the laws themselves; they were personified and made to will and act.

Even now these early stages in the history of thought can be traced by survivals in our language, survivals due to the ascription of moral qualities to matter. Thus gases are still sometimes said to obey or to disobey Boyle's Law as if it were an enactment for their guidance, and as if it set forth an ideal, the perfect gas, for their imitation. We still hear language which seems to imply that real gases are wanting in perfection, in that they fail to observe the exact letter of the law. I suppose on this view we should have to say that hydrogen is nearest to perfection; but then we should have to regard it as righteous over-much, a sort of Pharisee among gases which overshoots the mark in its endeavour to obey the law. Oxygen and nitrogen we may regard as good enough in the affairs of everyday life. But carbon dioxide and chlorine and the like are poor sinners which yield to temptation and liquefy whenever circumstances press at all hardly on them.

There is a similar ascription of moral qualities when we judge bodies according to their fulfilment of the purpose for which we use them, when we describe them as good or bad radiators, good or bad insulators, as if it were a duty on their part to radiate well, or insulate well, and as if there were failures on the part of nature to come up to the proper standard.

These are of course mere trivialities, but the reaction of language on thought is so subtle and far-reaching that, risking the accusation of pedantry, I would urge the abolition of all such picturesque terms. In our quantitative estimates let us be content with "high" or "low," "great" or "small," and let us remember that there is no such thing as a failure to obey a physical law. A broken law is merely a false description.

Concurrently with the change in our conception of physical law has come a change in our conception of physical explanation. We have not to go very far back to find such a statement as this—that we have explained anything when we know the cause of it, or when we have found out the reason why—a statement which is only appropriate on the psychical view. Without entering into any discussion of the meaning of cause, we can at least assert that that meaning will only have true content when it is concerned with purpose and will. On the purely physical or descriptive view, the idea of cause is quite out of place. In description we are solely concerned with the "how" of things, and their "why" we purposely leave out of account. We explain an event, not when we know "why" it happened, but when we show "how" it is like something else happening elsewhere or otherwhen—when, in fact, we can include it as a case described by some law already set forth. In explanation, we do not account *for* the event, but we improve our account *of* it by likening it to what we already knew.

For instance, Newton explained the falling of a stone when he showed that its acceleration towards the earth was similar to and could be expressed by the same law as the acceleration of the moon towards the earth.

He explained the air disturbance we call "sound" when he showed that the motions and forces in the pressure waves were like motions and forces already studied.

Franklin explained lightning when and so far as he showed that it was similar in its behaviour to other electric discharges.

Here I do not fear any accusation of pedantry in joining those who urge that we should adapt our language to the modern view. It would be a very real gain, a great assistance to clear thinking, if we could entirely abolish the word "cause," in physical description, cease to say "why" things happen unless we wish to signify an antecedent purpose, and be content to own that our laws are but expressions of "how" they occur.

The aim of explanation, then, is to reduce the number of laws as far as possible, by showing that laws, at first separated, may be merged in one; to reduce the number of chapters in the book of science by showing that some are truly mere sub-sections of chapters already written.

To take an old but never-worn-out metaphor, the physicist is examining the garment of nature, learning of how many, or rather of how few, different kinds of thread it is woven, finding how each separate thread enters into the pattern, and seeking from the pattern woven in the past to know the pattern yet to come.

How many different kinds of thread does nature use?

So far, we have recognised some eight or nine, the number of different forms of energy which we are still obliged to count as distinct. But this distinction we cannot believe to be real. The relations between the different forms of energy, and the fixed rate of exchange when one form gives place to another, encourage us to suppose that if we could only sharpen our senses, or change our point of view, we could effect a still further reduction. We stand in front of nature's loom as we watch the weaving of the garment; while we follow a particular thread in the pattern it suddenly disappears, and a thread of another colour takes its place. Is this a new thread, or is it merely the old thread turned round and presenting a new face to us? We can do little more than guess. We cannot get to the other side of the pattern, and our minutest watching will not tell us all the working of the loom.

Leaving the metaphor, were we true physicists, and physicists alone, we should, I suppose, be content to describe merely what we observe in the changes of energy. We should say, for instance, that so much kinetic energy ceases, and that so much heat appears, or that so much light comes to a surface, and that so much chemical energy takes its place. But we have to take ourselves as we are, and reckon with the fact that though our material is physical, we ourselves are psychical. And, as a mere matter of fact, we are not content with such discontinuous descriptions. We dislike the discontinuity and we think of an underlying identity. We think of the heat as being that which a moment before was energy of visible motion, we think of the light as changing its form alone and becoming itself the chemical energy. Then to our passive dislike to discontinuity we join our active desire to form a mental picture of what may be going on, a picture like something which we already know. Coming on these discontinuities our ordinary method of explanation fails, for they are not obviously like those series of events in which we can trace every step. We then imagine a constitution of matter and modifications of it corresponding to the different kinds of energy, such that the discontinuities vanish, and such that we can picture one form of energy passing into another and yet keeping the same in kind throughout. We are no longer content to describe what we actually see or feel, but we describe what we imagine we should see or feel if our senses were on quite another scale of magnitude and sensibility. We cease to be physicists of the real and become physicists of the ideal.

To form such mental pictures we naturally choose the sense which makes such pictures most definite, the sense of sight, and think of a constitution of matter which shall enable us to explain all the various changes in terms of visible motions and accelerations. We imagine a mechanical constitution of the universe.

We are encouraged in this attempt by the fact that the relations in this mechanical conception can be so exactly stated, that the equations of motion are so very definite. We have, too, examples of mechanical systems, of which we can give accounts far exceeding in accuracy the accounts of other physical systems. Compare, for instance, the accuracy with which we can describe and foretell the path of a planet with our ignorance of the movements of the atmosphere as dependent on the heat of the sun. The planet keeps to the astronomer's time-table, but the wind still bloweth almost where it listeth.

The only foundation which has yet been imagined for this mechanical explanation—if we may use "explanation" to denote the likening of our imaginings to that which we actually observe—is the atomic and molecular hypothesis of matter. This hypothesis arose so early in the history of science that we are almost tempted to suppose that it is a necessity of thought, and that it has a warrant of some higher order than any other hypothesis which could be imagined. But I suspect that if we could trace its early development we should find that it arose in an attempt to explain the phenomena of expansion and contraction, evaporation and solution. Were matter a continuum we should have to admit all these as simple facts, inexplicable in that they are like nothing else. But imagine matter to consist of a crowd of separate particles with interspaces. Contraction and expansion are then merely a drawing in and a widening out of the crowd. Solution is merely the mingling of two crowds, and evaporation merely a dispersal from the outskirts. The most evident properties of matter are then similar to what may be observed in any public meeting.

For ages the molecular hypothesis hardly went further than this. The first step onward was the ascription of vibratory motion to the atoms to explain heat. Then definite qualities were ascribed, definite mutual forces were called into play to explain elasticity and other properties or qualities of matter. But I imagine its first really great achievement was its success in explaining the law of combining proportions, and next to that we should put its success in explaining many of the properties of gases.

While light was regarded as corpuscular—in fact molecular, and while direct action at a distance presented no difficulty, the molecular hypothesis served as the one foundation for the mechanical representation of phenomena. But when it was shown that infinitely the best account of the phenomena of light could be given on the supposition that it consisted of waves, something was needed, as Lord Salisbury has said, to wave, both in the interstellar and in the intermolecular spaces. So the hypothesis of an ether was developed, a necessary complement of that form of the molecular hypothesis in which matter consists of discrete particles with matter-free intervening spaces.

Then Faraday's discovery of the influence of the dielectric medium in electric actions led to the general abandonment of the idea of action at a distance, and the ether was called in to aid matter in the explanation of electric and magnetic phenomena. The discovery that the velocity of electro-magnetic waves is the same as that of light-waves is at least circumstantial evidence that the same medium transmits both.

I suppose we all hope that some time we shall succeed in attributing to this medium such further qualities that it will be able to enlarge its scope and take in the work of gravitation.

The mechanical hypothesis has not always taken this dualistic form of material atoms and molecules, floating in a quite distinct ether. I think we may regard Boscovich's theory of point-centres surrounded by infinitely extending atmospheres of force as really an attempt to get rid of the dualism, and Faraday's theory of point centres with radiating lines of force is only Boscovich's theory in another form. But Lord Kelvin's vortex-atom theory gives us a simplification more easily thought of. Here all space is filled with continuous fluid—shall we say a fluid ether?—and the atoms are mere loci of a particular type of motion of this frictionless fluid. The sole differences in the atoms are differences of position and motion. Where there are whirls, we call the fluid matter; where there are no whirls, we call it ether. All energy is energy of motion. Our visible kinetic energy, $MV^2/2$, is energy in and round the central whirls; our visible energy of position, our potential energy, is energy of motion in the outlying regions.

A similar simplification is given by Dr. Larmor's hypothesis, in which, again, all space is filled with continuous substance all of one kind, but this time solid rather than fluid. The atoms are loci of strain instead of whirls, and the ether is that which is strained.

So, as we watch the weaving of the garment of nature, we resolve it in imagination into threads of ether spangled over with beads of matter. We look still closer, and the beads of matter vanish; they are mere knots and loops in the threads of ether.

The question now faces us—How are we to regard these hypotheses as to the constitution of matter and the connecting ether? How are we to look upon the explanations they afford? Are we to put atoms and ether on an equal footing with the phenomena observed by our senses, as truths to be investigated for their own sake? Or are they mere tools in the search for truth, liable to be worn out or superseded?

That matter is grained in structure is hardly more than an expression of the fact that in very thin layers it ceases to behave as in thicker layers. But when we pass on from this general statement and give definite form to the granules, or assume definite qualities to the intergranular cement, we are dealing with pure hypotheses.

It is hardly possible to think that we shall ever see an atom or handle the ether. We make no attempt whatever to render them evident to the senses. We connect observed conditions and changes in gross visible matter by invisible molecular and ethereal machinery. The changes at each end of the machinery of which we seek to give an account are in gross matter, and this gross matter is our only instrument of detection, and we never receive direct sense-impressions of the imagined atoms or the intervening ether. To strictly descriptive physicists their only use and interest would lie in their service in prediction of the changes which are to take place in gross matter.

It appears quite possible that various types of machinery might be devised to produce the known effects. The type we have adopted is undergoing constant minor changes, as new discoveries suggest new arrangements of the parts. Is it utterly beyond possibility that the type itself should change?

The special molecular and ethereal machinery which we have designed, and which we now generally use, has been designed because our most highly developed sense is our sense of sight. Were we otherwise, had we a sense more delicate than sight, one affording us material for more definite mental presentation, we might quite possibly have constructed very different hypotheses. Though, as we are, we cannot conceive any higher type than that founded on the sense of sight, we can imagine a lower type, and by way of illustration of the point let us take the sense of which my predecessor spoke last year—the sense of smell. In us it is very undeveloped. But let us imagine a

being in whom it is highly cultivated, say a very intellectual and very hypothetical dog. Let us suppose that he tries to frame an hypothesis as to light. Having found that his sense of smell is excited by surface exhalations, will he not naturally make and be content with a corpuscular theory of light? When he has discovered the facts of dispersion, will he not think of the different colours as different kinds of smell—insensible, perhaps, to him, but sensible to a still more highly gifted, still more hypothetical, dog?

Of course, with our superior intellect and sensibility, we can see where his hypothesis would break down; but unless we are to assume that we have reached finality in sense development, the illustration, grotesque as it may be, will serve to show that our hypotheses are in terms of ourselves rather than in terms of nature itself, they are ejective rather than objective, and so they are to be regarded as instruments, tools, apparatus only to aid us in the search for truth.

To use an old analogy—and here we can hardly go except upon analogy—while the building of nature is growing spontaneously from within, the model of it, which we seek to construct in our descriptive science, can only be constructed by means of scaffolding from without, a scaffolding of hypotheses. While in the real building all is continuous, in our model there are detached parts which must be connected with the rest by temporary ladders and passages, or which must be supported till we can see how to fill in the understructure. To give the hypotheses equal validity with facts is to confuse the temporary scaffolding with the building itself.

But even if we take this view of the temporary nature of our molecular and ethereal imaginings, it does not lessen their value, their necessity to us.

It is merely a true description of ourselves to say that we must believe in the continuity of physical processes, and that we must attempt to form mental pictures of those processes the details of which elude our observation. For such pictures we must frame hypotheses, and we have to use the best material at command in framing them. At present there is only one fundamental hypothesis—the molecular and ethereal hypothesis—in some such form as is generally accepted.

Even if we take the position that the form of the hypothesis may change as our knowledge extends, that we may be able to devise new machinery—nay, even that we may be able to design some quite new type to bring about the same ends—that does not appear to me to lessen the present value of the hypothesis. We can recognise to the full how well it enables us to group together large masses of facts which, without it, would be scattered apart, how it serves to give working explanations, and continually enables investigators to think out new questions for research. We can recognise that it is the symbolical form in which much actual knowledge is cast. We might almost as well quarrel with the use of the letters of the alphabet, inasmuch as they are not the sounds themselves, but mere arbitrary symbols of the sounds.

In this country there is no need for any defence of the use of the molecular hypothesis. But abroad the movement from the position in which hypothesis is confounded with observed truth has carried many through the position of equilibrium equally far on the other side, and a party has been formed which totally abstains from molecules as a protest against immoderate indulgence in their use. Time will show whether these protesters can do without any hypothesis, whether they can build without scaffolding or ladders. I fear that it is only an attempt to build from balloons.

But the protest will have value if it will put us on our guard against using molecules and the ether everywhere and everywhere. There is, I think, some danger that we may get so accustomed to picturing everything in terms of these hypotheses that we may come to suppose that we have no firm basis for the facts of observation until we have given a molecular account of them, that a molecular basis is a firmer foundation than direct experience.

Let me illustrate this kind of danger. The phenomena of capillarity can, for the most part, be explained on the assumption of a liquid surface tension. But if the subject is treated merely from this point of view, it stands alone—it is a portion of the building of science hanging in the air. The molecular hypothesis then comes in to give some explanation of the surface tension, gives, as it were, a supporting understructure connecting capillarity with other classes of phenomena. But here, I think, the hypothesis should stop, and such phenomena as can be explained by the surface tension should be so explained without reference to molecules. They should not be brought in again till the surface-tension explanation fails. It is necessary to bear in mind what part is scaffolding, and what is the building itself, already firm and complete.

Or, as another illustration, take the Second Law of Thermodynamics. I suspect that it is sometimes supposed that a molecular theory from which the Second Law could be deduced would be a better basis for it than the direct experience on which it was founded by Clausius and Kelvin, or that the mere imagining of a Maxwell's sorting demon has already disproved the universality of the law; whereas he is a mere hypothesis grafted on a hypothesis, and nothing corresponding to his action has yet been found.

There is more serious danger of confusion of hypothesis with fact in the use of the ether: more risk of failure to see what is accomplished by its aid. In giving an account of light, for instance, the right course, it appears to me, is to describe the phenomena and lay down the laws under which they are grouped, leaving it an open question what it is that waves, until the phenomena oblige us to introduce something more than matter, until we see what properties we must assign to the ether, properties not possessed by matter, in order that it may be competent to afford the explanations we seek. We should then realise more clearly that it is the constitution of matter which we have imagined, the hypothesis of discrete particles which obliges us to assume an intervening medium to carry on the disturbance from particle to particle. But the vortex-atom hypothesis and Dr. Larmor's strain-atom hypothesis both seem to indicate that we are moving in the direction of the abolition of the distinction between matter and ether, that we shall come to regard the luminiferous medium, not as an attenuated substance here and there encumbered with detached blocks—the molecules of matter—but as something which in certain places exhibits modifications which we term matter. Or starting rather from matter, we may come to think of matter as no longer consisting of separated granules, but as a continuum with properties grouped round the centres, which we regard as atoms or molecules.

Perhaps I may illustrate the danger in the use of the conception of the ether by considering the common way of describing the electro-magnetic waves, which are all about us here, as ether waves. Now in all cases with which we are acquainted, these waves start from matter; their energy before starting was, as far as we can guess, energy of the matter between the different parts of the source, and they manifest themselves in the receiver as energy of matter. As they travel through the air, I believe that it is quite possible that the electric energy can be expressed in terms of the molecules of air in their path, that they are effecting atomic separations as they go. If so, then the air is quite as much concerned in their propagation as the ether between its molecules. In any case, to term them ether waves is to prejudge the question before we have sufficient evidence.

Unless we bear in mind the hypothetical character of our mechanical conception of things, we may run some risk of another danger—the danger of supposing that we have something more real in mechanical than in other measurements. For instance, there is some risk that the work measure of specific heat should be regarded as more fundamental than the heat measure, in that heat is truly a "mode of motion." On the molecular hypothesis, heat is no doubt a mixture of kinetic energy and potential energy of the molecules and their constituents, and may even be entirely kinetic energy; and we may conceivably in the future make the hypothesis so definite that, when we heat a gramme of water 1°, we can assign such a fraction of an erg to each atom. But look how much pure hypothesis is here. The real superiority of the work measure of specific heat lies in the fact that it is independent of any particular substance, and there is nothing whatever hypothetical about it.[1]

[1] This risk of imagining one particular kind of measure more real than another, more in accordance with the truth of things, may be further illustrated by the common idea that mass-acceleration is the only way to measure a force. We stand apart from our mechanical system and watch the motions and the accelerations of the various parts, and we find that mass-accelerations have a certain significance in our system. If we keep ourselves outside the system and only use our sense of sight, then mass-acceleration is the only way of describing that behaviour of one body in the presence of others which we term force on it. But if we go about in the system and pull and push bodies, we find that there is another conception of force, in which another sense than sight is concerned—another mode

Another illustration of the illegitimate use of our hypothesis, as it appears to me, is in the attempt to find in the ether a fixed datum for the measurement of material velocities and accelerations, a something in which we can draw our coordinate axes so that they will never turn or bend. But this is as if, discontented with the movement of the earth's pole, we should seek to find our zero lines of latitude and longitude in the Atlantic Ocean. Leaving out of sight the possibility of ethereal currents which we cannot detect, and the motions due to every ray of light which traverses space, we could only fix positions and directions in the ether by buoying them with matter. We know nothing of the ether, except by its effects on matter, and, after all, it would be the material buoys which would fix the positions and not the ether in which they float.

The discussion of the physical method, with its descriptive laws and explanations, and its hypothetical extension of description, leads us on to the consideration of the limitation of its range. The method was developed in the study of matter which we describe as non-living, and with non-living matter the method has sufficed for the particular purposes of the physicist. Of course only a little corner of the universe has been explored, but in the study of non-living matter we have come to no impassable gulfs, no chasms across which we cannot throw bridges of hypothesis. Does the method equally suffice when it is applied to living matter? Can we give a purely physical account of such matter, likening its motions and changes to other motions and changes already observed, and so explaining them? Can we group them in laws which will enable us to predict future conditions and positions? The ancient question never answered, but never ceasing to press for an answer.

Having faith in our descriptive method, let us use it to describe our real attitude on the question. Do we, or do we not, as a matter of fact, make any attempt to apply the physical method to describe and explain those motions of matter which on the psychical view we term voluntary?

Any commonplace example, and the more commonplace the more is it to the point, will at once tell us our practice, whatever may be our theory. For instance, a steamer is going across the Channel. We can give a fairly good physical account of the motion of the steamer. We can describe how the energy stored in the coal passes out through the boiler into the machinery, and how it is ultimately absorbed by the sea. And the machinery once started, we can give an account of the actions and reactions between its various parts and the water, and if only the crew will not interfere, we can predict with some approach to correctness how the vessel will run. All these processes can be likened to processes already studied—perhaps on another scale—in our laboratories, and from the similarities prediction is possible. But now think of a passenger on board who has received an invitation to take the journey. It is simply a matter of fact that we make no attempt at a complete physical account and explanation of those actions which he takes to accomplish his purpose. We trace no lines of induction in the ether connecting him with his friends acrcss the Channel, we seek no law of force under which he moves. In practice the strictest physicist abandons the physical view, and replaces it by the psychical. He admits the study of purpose as well as the study of motion.

He has to admit that here his physical method of prediction fails. In physical observations one set of measurements may lead to the prediction of the results of another set of measurements. The equations expressing the laws imply different observations with some definite relation between their results, and if we know one set of observations and that definite relation we can predict the result of the other set. But if we take the psychical view of actions, we can only measure the actions. We have no independent means of studying and measuring the motions which preceded the actions, we can only estimate their value by the consequent actions. If we formed equations, they would be mere identities with the same terms on either side.

The consistent and persistent physicist, finding the door closed against him, finding that he has hardly a sphere of influence left to him in the psychical region, seeks to apply his methods in another way by assuming that if he knew all about the molecular positions and motions in the living matter, then the ordinary physical laws could be applied and the physical conditions at any future time could be predicted. He would say, I suppose, with regard to the Channel passenger, that it is absurd to begin with the most complicated mechanism, and seek to give a physical account of that. He would urge that we should take some lower form of life where the structure and motions are simpler, and apply the physical methods to that.

of measurement much more ancient and still far more extensively used —the measurement by weight supported. Each method has its own range; each is fundamental in that range. It is one of the great practical problems n physics to make the pendulum give us the exact ratio of the units in the wo systems.

Well, then, let us look for the physical explanation of any motion which we are entitled from its likeness to our own action to call a voluntary motion. Must we not own that even the very beginning of such explanation is as yet non-existent? It appears to me that the assumption that our methods do apply, and that purely physical explanation will suffice to predict all motions and changes, voluntary and involuntary, is at present simply a gigantic extra-polation, which we should unhesitatingly reject if it were merely a case of ordinary physical investigation. The physicist when thus extending his range is ceasing to be a physicist, ceasing to be content with his descriptive methods in his intense desire to show that he is a physicist throughout.

Of course we may describe the motions and changes of any type of matter after the event, and in a purely physical manner. And as Prof. Ward has suggested, in a most important contribution to this subject which he has made in his recently published "Gifford Lectures" ("Naturalism and Agnosticism," *The Gifford Lectures*, 1896–98, vol. ii. p. 71), where ordinary physical explanations fail to give an account of the motions, we might imagine some structure in the ether, and such stresses between the ether and matter that our physical explanations should still hold. But, as Prof. Ward says, such ethereal constructions would present no warrant for their reality or consistency. Indeed they would be mere images in the surface of things to account for what goes on in front of the surface, and would have no more reality than the images of objects in a glass.

If we have full confidence in the descriptive method, as applied to living and non-living matter, it appears to me that up to the present it teaches us that while in non-living matter we can always find similarities, that, while each event is like other events, actual or imagined, in a living being there are always dissimilarities. Taking the psychical view—the only view which we really do at present take—in the living being there is always some individuality, something different from any other living being, and full prediction in the physical sense, and by physical methods, is impossible. If this be true, the loom of nature is weaving a pattern with no mere geometrical design. The threads of life, coming in we know not where, now twining together, now dividing, are weaving patterns of their own, ever increasing in intricacy, ever gaining in beauty.

## SECTION B.

### CHEMISTRY.

OPENING ADDRESS BY DR. HORACE T. BROWN, F.R.S., PRESIDENT OF THE SECTION.

THE subject which I have chosen for my Address is the fixation of carbon by plants, one which is the common meeting ground of chemistry, physics and biology. I must, however, confine myself only to certain aspects of the question, since it is manifestly impossible to fully discuss the whole of a subject of such magnitude and importance within the time at my disposal.

We have become so accustomed to the idea that the higher plants derive *the whole* of their carbon from atmospheric sources that we are apt to forget how very indirect is the nature of much of the experimental evidence on which this belief is founded. There can, of course, be no doubt that the primary source of the organic carbon of the soil, and of the plants growing on it, is the atmosphere; but of late years there has been such an accumulation of evidence tending to show that the higher plants are capable of being nourished by the direct application of a great variety of ready-formed organic compounds, that we are justified in demanding further proof that the stores of organic substances in the soil must necessarily be oxidised down to the lowest possible point before their carbon is once more in a fit state to be assimilated.

It was the hope of gaining more direct evidence on this important question which led me some time ago to attack the problem experimentally in conjunction with Mr. F. Escombe, the resources of the Jodrell Laboratory at Kew having been

kindly put at our disposal by Sir W. Thiselton-Dyer and Dr. D. H. Scott. Up to the present time our experiments have not been carried far enough to enable us to give a positive answer to the main question, but they have already suggested a new method of attack which will enable us in the future to determine, with a fair amount of certainty, whether any particular plant, growing under perfectly natural conditions, derives any appreciable portion of its carbon from any other source than the gaseous carbon dioxide of the atmosphere.

During the course of the inquiry, many interesting side issues have been raised which we believe to be of some importance in their bearing on the processes of plant nutrition, and it is to a consideration of these that I intend to devote the greater part of my Address.

I must, however, in the first place indulge in a little historical retrospect, and am the more tempted to do this, as far as the early pioneers in this branch of knowledge are concerned, since a critical study of their writings has shown me very clearly that the relative merits of some of these older workers, and the respective parts which they took in founding the true theory of assimilation, have in our own time been much misrepresented by more than one historian of science whose name carries great weight.

There is no chapter in the history of scientific discovery of greater abiding interest than that which was opened by Priestley in 1771, when he commenced his work on the influence of plants on the composition of the air around them. It has often been assumed that these experiments of Priestley, which were unquestionably the starting-point for all succeeding workers, were the result of some haphazard method of working, and of one of those happy chances to which he is in the habit of attributing some of his most important discoveries. However much the element of chance entered into some of his work, and in this respect I think Priestley often does himself injustice, the discovery of the amelioration of vitiated air by plants was certainly not a case of this kind. Of all his contemporaries belonging to the old school of chemistry, Priestley had the clearest conception of the processes of animal respiration and of their identity with the process of combustion. This is clearly shown by his "Observations on Respiration and the Use of the Blood," which he presented to the Royal Society in 1776 This memoir, written of course from the phlogistic point of view, only requires translating into the language of the newer chemistry to be an accurate statement of the main facts of animal respiration. We have it on Priestley's own authority that it was these studies which produced in his mind a conviction that there must be some provision in nature for dephlogisticating the air which was constantly being vitiated by the processes of respiration, combustion and putrefaction, and for rendering it once more fit for maintaining animal life. In his search for this compensating influence, which he justly regarded as one of the most important problems of natural philosophy, he made many attempts to bring back the vitiated air to its original state by agitating it with water, and by submitting it to the continued action of light and heat, and it was in the course of these systematic attempts that he was led to study the influence of plants in this direction.

It was in the month of August 1771 that he made the memorable experiments at Leeds of immersing sprigs of mint in air which had been vitiated by the burning of a candle or by animal respiration. To quote his own words, this observation led him "to conclude that plants, instead of affecting the air in the same manner with animal respiration, reverse the effects of breathing, and tend to keep the atmosphere sweet and wholesome when it is become noxious in consequence of animals either living or breathing, or dying and putrefying in it." That he was fully convinced that these observations, which he repeated and amplified in the following year. presented the true key to the problem, is sufficiently shown by another passage in which he says: "These proofs of the partial restoration of air by plants in a state of vegetation, though in a confined and unnatural situation, cannot but render it highly probable that the injury which is continually done to the atmosphere by the respiration of such a number of animals, and the putrefaction of such masses of both vegetable and animal matter, is, in part at least, repaired by the vegetable creation; and notwithstanding the prodigious mass of air that is corrupted daily by the above causes, yet if we consider the immense profusion of vegetables upon the face of the earth growing in places suited to their nature, and consequently at full liberty to exert all their powers, both inhaling and exhaling, it can hardly be thought but that it may be a sufficient counterbalance to it, and that the remedy is adequate to the evil."

Between the time of Priestley temporarily relinquishing his experiments in this direction in 1772 and his resumption of them in 1778, owing to the adverse criticism of Scheele and others, he had discovered dephlogisticated air or oxygen, and had elaborated his method for ascertaining the purity of air, or its richness in oxygen, by determining its diminution in volume after mixing with an excess of nitric oxide over water.[1] This method gave, of course, a much greater degree of precision to his results than was attainable in his earlier work, where the purity of the air at the end of an experiment was only determined by ascertaining if it would support the combustion of a candle or allow a small animal to live in it.

The results of his later work were published in 1779, and were not altogether confirmatory of those arrived at six years before. It is true that he generally found evidence of an evolution of oxygen by the plants, but occasionally the air was less "pure" at the end of an experiment than it was at the beginning, and this occurred in a sufficient number of cases to Dr. Priestley to doubt to some extent the accuracy of his previous conclusions. On the whole, however, he still thinks it *probable* that the vegetation of healthy plants has a salutary effect on the air in which they grow.

The reason for this want of complete consistency in these later experiments was, of course, his failure at that time to recognise the important influence of *light* in bringing about the evolution of oxygen, an explanation which was given shortly afterwards by Ingen-Housz.

Priestley's attention was now taken up with another observation, which led him within a very short distance indeed of the discovery that the evolution of oxygen by plants is conditioned, not only by a sufficient degree of illumination, but also by the pre-existence of carbon dioxide. It is the more necessary to treat of this point somewhat in detail, since it is a part of his work which has received but scanty justice at the hands of recent writers, who have apparently failed to see how much our modern conceptions of plant nutrition really owe to the initiative of Priestley. In his "History of Botany," Sachs deals very unfairly with Priestley in this respect, owing to a want of intimate knowledge of his writings, and to the lack of anything like perspective in estimating the relative merits of his contemporaries Ingen-Housz and Senebier, whose position can only be completely understood after a careful study of their numerous original memoirs, some of which are by no means readily accessible.

In the course of his experiments on plants partially immersed in water more or less fully impregnated with "fixed air," Priestley had observed a fact which had not escaped the notice of Bonnet at an earlier date, that bubbles of gas arose spontaneously from the leaves and stems, and it occurred to him that an examination of the nature of this gas by means of his new eudiometric process ought to settle the question whether plants really do contribute in any way to the purification of ordinary air. It was in June 1778 that he put this to the test, and he found that the air thus liberated was much richer in oxygen than ordinary air. On removing the plants, he found to his astonishment that the water in which they had been placed, and which had a considerable amount of "green matter" adhering to the sides of the phials, still continued to evolve a gas which increased in amount when the vessels were placed in sunlight. On testing this gas with his eudiometric process, he found that it consisted to a great extent of "dephlogisticated air" or oxygen; in fact, from the experimental results which he gives it is evident that the gas contained from 74 to 85 per cent. of oxygen. Having observed that the "green matter" appeared much more readily in pump water than in rain or river water, and knowing that pump water contained considerable amounts of "fixed air," he was led to make a series of experiments with water artificially impregnated with carbon dioxide, which left no doubt in his mind that the production of the "green matter," and the evolution of the dephlogisticated air were in some way due to the presence of "fixed air." Up to this point Priestley was following a path which seemed about to lead him to a complete solution of his previous difficulties. He had beyond all question succeeded in showing that the evolution of oxygen was not only dependent on the pre-existence of carbon dioxide, but that light was also required

[1] Nitric oxide was discovered by Priestley in 1772, and was described by him under the name of "nitrous air."

for the process. It only wanted, in fact, the recognition of the vegetable nature of the alga which constituted his "green substance" to bring these observations into line with his previous work, and to complete a discovery which would have eclipsed in importance all the others with which Priestley's name is associated. It was just this one step which he most provokingly failed to take. It is true that he examined the "green substance" under the microscope, but owing to want of skill in the use of the instrument, and also to his defective eyesight, he was unable to determine its true nature, and unfortunately adopted the view that it had merely a mechanical action in separating the oxygen from the water, and, to use his own words, that "it was only a circumstance preceding the spontaneous emission of the air from water." He was, in fact, now inclined to regard the process as a purely chemical one, due to the direct action of light on the carbon dioxide dissolved in the water.

But this was by no means Priestley's final view, as shown by a further description of his experiments on plants set forth in the new edition of his works published in 1790, where he clearly recognised the error into which he had been led.[1] Meanwhile the subject had been taken up by two other observers, Ingen-Housz and Senebier, and in order to thoroughly understand the respective shares which these men took in advancing our knowledge of the assimilatory process, it is necessary to consult, not only their books, but also the numerous scattered memoirs which appeared at intervals between the years 1779 and 1800.

To Ingen-Housz must unquestionably be awarded the merit of having experimentally demonstrated that the amelioration of the surrounding air by plants is not, as Priestley at first believed, due to vegetative action *per se*, but is dependent on the access of light of a sufficient degree of intensity, and, moreover, that the power is confined to the green parts of the plants. At the same time, whilst recognising, as Priestley had done before him, that the combined action of plants and light on the air was a dephlogisticating process, he did not know, until after its demonstration by Senebier, that the particular form of phlogisticated air which was essential to plants was "fixed air" or carbon dioxide. In fact, Ingen-Housz had but a slender knowledge of the chemistry of his day, so much so indeed that he constantly confuses "phlogisticated air" or nitrogen with "fixed air," and attributes the source of the evolved oxygen either to air imprisoned within the leaf, or, in the case of submerged plants, to a metamorphosis of the water itself. I must, however, recall the fact that Ingen-Housz was the first to show that the green parts of plants in the dark, and the roots both in the light and in darkness, vitiate the air in the same way as animals do. On the strength of these experiments, he is generally given credit for having first observed the true respiration of plants, but I cannot avoid the conclusion that, in the controversy which ensued on this point between Ingen-Housz and Senebier, the adverse criticisms of the latter were well-founded. Whilst not denying that plants in the dark have some mephitic influence on the air around them, Senebier maintained that the greater part of the observed effect was due to a fermentative action set up in the large bulk of leaves which Ingen-Housz employed. Certainly some of the results appear to be largely in excess of those we should now expect to obtain from respiratory processes only.[2]

Senebier's work falls between the years 1782 and 1800. The fact that he was an early convert to the new ideas and generalisations of Lavoisier gives his views on plant nutrition far greater precision than those of Priestley and Ingen-Housz. His experiments, for the most part well devised, proved beyond all doubt that the oxygen disengaged from submerged and isolated plants could not be derived from air contained in the leaf parenchyma, but that it depended on the pre-existence of carbon dioxide, and that its evolution was strictly proportional to the amount of carbon dioxide which the water contained.

Although positive experimental proof was still wanting that aërial plants also derive their carbon from carbon dioxide, Senebier regarded this as extremely probable; but, taking into consideration the small amount of this gas present in the atmosphere, he concluded that it must reach the plant by the roots and leaves entirely in a state of solution in water.

The work of Priestley, Senebier, and Ingen-Housz fortunately attracted the attention of a young chemist of high attainments, who, within a period of less than ten years, did more for the advancement of vegetable physiology than any single observer before or since his time. Théodore de Saussure, the second of that illustrious name, and the son of the famous explorer and natural philosopher, commenced his researches about the year 1796, and in 1804 published his "Recherches Chimiques sur la Végétation," a modest little octavo volume of some 300 pages which must certainly take rank as one of the great classics of scientific literature, and one of the most remarkable books of the century.

De Saussure was a past master in the art of experiment, and the methods which he devised for demonstrating the influence of water, air and soil on vegetation have been the models on which all such investigations have been conducted ever since. It is indeed very difficult, when reading this masterly essay, to bear in mind that it was not written fifty or sixty years later than the date on its title-page, so essentially modern are its modes of expression and reasoning, and so far is the author in advance of his contemporaries. It is to this work we must refer for the first experimental proof that plants derive at any rate the greater part of their carbon from the surrounding atmosphere. This was shown by De Saussure by a variety of quantitative experiments of a sufficient degree of accuracy to bring out the great leading facts. By making known mixtures of carbon dioxide and air, and submitting them to the action of plants in sunlight, he was able, not only to show that the gaseous carbon dioxide was decomposed and the carbon assimilated, but also that the volume of oxygen disengaged was approximately equal to that of the carbon dioxide decomposed.[1] He also showed that plants growing in the open in moist sand, or in distilled water, and therefore under conditions in which they could not derive any carbon from other than atmospheric sources, not only materially increased in dry weight, but contained much more carbon at the close of the experiment than at the beginning, and had also fixed an appreciable amount of water in the process. That atmospheric carbon dioxide is not only beneficial to plants in sunlight, but is also essential to their very existence, De Saussure proved by introducing an absorbent of this gas into the vessel containing a plant or the branch of a tree rooted naturally in the soil. Under these conditions, the portions of the plant enclosed always died. He also ascertained by experiment the increase in dry weight of a sunflower plant during four months of natural growth; and knowing approximately the amount of water transpired during that period, and the maximum amount of solids which this transpired water could possibly introduce into the plant, he calculated that these solids, and the carbon dioxide in solution in the transpiration water, fell far short of accounting for the observed increase in the dry weight of the plant. This increase must, therefore, be mainly due to the fixation of atmospheric carbon dioxide and water.

It is certainly a remarkable fact that the rigid experimental proofs which De Saussure brought forward in support of his views did not carry conviction to the minds of every one. His book, however, suffered the fate of many others which have appeared in advance of their time. It is true that De Saussure's doctrines were always kept alive by the advanced physiologists of the French school, such as De Candolle and Dutrochet, but when Liebig first turned his attention to the subject he found the field in possession of the humus theory of Treviranus, a theory which no longer took any account of the decomposition of carbon dioxide by the leaves, but which de-

[1] The view which was taken by Priestley's contemporaries of his position with regard to the discovery of the fundamental facts is well exemplified by the following remarks taken from a paper published by Ingen-Housz in 1784 (*Annales de Physique*, xxiv. 44). "C'est à M. Priestley seul que nous devons la grande découverte que les végétaux possèdent le pouvoir de corriger l'air mauvais et d'ameliorer l'air commun: c'est lui qui nous en a ouvert la porte. J'ai été assez constamment attaché à ce beau système, dans le temps que lui même, par trop peu de prédilection pour ses propres opinions, paroissoit chanceler."

[2] It is by no means uncommon to find Ingen-Housz put forward as the discoverer of the fixation of carbon by plants from carbon dioxide. This claim is generally based on certain statements made in his essay on the "Food Plants and the Renovation of the Soil," published in 1796 as an appendix to the outlines of the fifteenth chapter of the "Proposed General Report from the Board of Agriculture." All that is good and sound in this essay is taken from Senebier's papers without any acknowledgment, but, in appropriating ideas which he evidently understands very imperfectly, he has built up a system of plant economy which is almost unintelligible.

[1] Although clearly indicating that no change of volume occurred in the mixture of air and carbon dioxide so treated, his final analytical results show a small apparent evolution of nitrogen. This was due to the eudiometric methods he employed, methods, it is true, far superior in point of accuracy to those of his predecessors, but still necessarily imperfect.

rived the whole of the elements of the growing plant from a solution of the soil extract taken up by the roots. We may well say with Sachs, "nothing can be conceived more deplorable than this theory of nutrition; it would have been bad at the end of the seventeenth century, it is difficult to believe that it could have been published thirty years after De Saussure's work." It is well known how by the cogency of his reasoning and the force of his genius Liebig successfully overthrew this heresy, and once more established the doctrine of carbon assimilation as taught by De Saussure; and the accurate work of Boussingault, who, whilst elaborating far more delicate analytical processes than were possessed by chemists in the early days of the century, still in the main used De Saussure's methods, gave the final death-blow to the humus theory, at any rate in the crude form in which it was presented by its originators. No one since that time has questioned the fact that green plants owe the greater part of their carbon to atmospheric sources, and the accumulated experience of two succeeding generations of workers has added proof on proof of the correctness of this great generalisation.

But whilst it cannot be doubted that green plants devoid of parasitic or saprophytic habit derive the principal part of their carbon from the air, is the experimental evidence at present so complete as to exclude all other sources of supply? De Saussure himself certainly left the door open to such a possibility, and although Boussingault held a different view, we find Sachs as late as 1865 maintaining that it is not contrary to the generally accepted theory of assimilation to suppose that there are chlorophyllous plants which decompose carbon dioxide and at the same time absorb ready-formed organic substances whose carbon they utilise in the formation of new organs.

Up to comparatively recently there was little or no experimental evidence to justify this supposition, for the early experiments of De Saussure on the influence of solutions of sugar, and of other organic substances, on growing plants, although very suggestive, were not of a sufficiently precise nature to lead to any conclusions, and we must come down to within fifteen years of the present time for anything like a demonstration that the green organs of plants can, under favourable conditions, build up their tissue from already elaborated carbon compounds just as do the fungi and the non-chlorophyllous plants generally.

The active centres of the decomposition of carbon dioxide in green leaves are the chlorophyll corpuscles or chloroplastids, and the first visible indication of this decomposition is the formation within these chloroplastids of minute granules of starch whose presence can be shown by suitable micro-chemical means. I have elsewhere discussed the question of how far the appearance of this starch is dependent on the pre-existence of other carbohydrates of a simpler constitution, and also the probability that the whole of the products of assimilation do not necessarily pass through the form of starch: this is a subject which need scarcely concern us at the present moment; it is sufficient to draw attention to the main fact that in an assimilating cell the chloroplastids, in the vast majority of cases, give rise to these minute starch granules, which once more disappear when the plant is placed in darkness, or when the air around it is deprived of carbon dioxide. Now in 1883 Böhm made the interesting discovery that when green leaves are placed in the dark until the starch of their chloroplastids has completely disappeared, there is a reappearance of starch when the cut end of the leaf-stalk is immersed in a solution of cane sugar and of dextrose, or when the leaf is brought directly in contact with solutions of these substances. He found, in fact, that the elements of the cell which, under ordinary circumstances, manufacture their materials for plant growth by the reduction of carbon dioxide under the influence of sunlight, can, under other conditions, supply their requirements from suitable ready-formed organic substances. These observations of Böhm were fully confirmed two years later by Schimper, and were subsequently much extended by A. Meyer and E. Laurent, who found that fructose, maltose, mannitol, dulcitol, and glycerol could also contribute directly to the nutrition of leaves.

Bokorny, working with *Spirogyra* immersed in dilute solutions, found that starch production in the chlorophyll bodies could be induced by a large number of organic substances, including, amongst many others, asparagin, citric, tartaric, and lactic acids, leucine, tyrosine, and peptone.[1]

Very much more to the point are the experiments of Acton, made in 1889, and the still more recent work of J. Laurent and of Mazé.

In his experiments on terrestrial plants, Acton, after depleting them of starch, immersed the cut branches or roots, as the case might be, in culture fluids containing certain organic substances, and took precautions to prevent any normal assimilation from taking place by depriving the air around the plant of any trace of carbon dioxide. He was not able to show the direct nutritive influence of so large a range of substances as Bokorny had done for *Spirogyra*, but his results leave no room for doubt that several of the carbohydrates, and even glycerine, can be absorbed by the roots, and can contribute to the nutrition of the green parts. Acton tried, amongst other substances, an "extract of natural humus," which was an aqueous solution of the extractives of a light soil which are soluble in dilute alcohol. This extract was found to be effective in producing a small quantity of starch in the leaves, and it evidently contained some substance or substances directly assimilable by the plant.

Apparently without knowing anything of this work of Acton, J. Laurent has recently made a series of experiments on the culture of the maize plant in mineral solutions containing saccharose, glucose, or invert-sugar, and in this way has not only obtained, as Acton had done before him, evidence of the active formation of starch in the leaves, but has also found a very notable increase in the dry weight of the plant. Although assimilation of the carbohydrate may under these circumstances go on in darkness, Laurent found that the process was much enhanced when light had access to the plant. Mazé, within the last few months, has obtained even more pronounced effects of this kind.

When all these new facts are taken into consideration, I think they justify what I have already said, that we ought to demand more direct evidence than is at present available before we accept the view that the majority of chlorophyllous plants take in *the whole* of their carbon from the atmosphere. In the cycle of change which the organic matter of the soil is constantly undergoing under the influence of micro-organisms, it seems by no means improbable that intermediate substances may be formed which in some measure directly contribute to the nutrition of the higher plants, and we must also by no means lose sight of the possible effect, in the same direction, of the symbiotic union of certain fungi with the root extremities of many plants, the Mycorhizæ, whose functions are still so imperfectly understood. Then, again, we must remember that we have another possible extra-atmospheric source of carbon dioxide in the transpiration water of the plant, which is derived from a soil whose gases may contain 5 per cent. or more of carbon dioxide. From the amount of water transpired in a given time, and an application of the law of partial pressures, it may be readily shown that the supply of carbon dioxide to the aërial organs of a plant from this source is by no means negligible.

Before these problems can be attacked for a particular plant with any hope of success, it is clear that we must have some means of establishing an accurate debtor and creditor account as between the plant and the surrounding atmosphere, and this account must extend over a sufficiently long period, and allow of an accurate balance being struck with the amount of carbon found in the plant at the end of the experiment.

Up to within a few years ago we had no means of even approximately determining the actual rate at which the assimilatory process goes on in a plant other than that afforded by its increase in weight in a given time. Such experiments, necessarily extending over weeks or months, can, at the best, only give us certain average results, and consequently afford no measure of the activity of assimilation under fixed conditions of insolation. In the year 1884, Sachs, who had for some time been at work on the formation of starch in leaves under the action of sunlight, found that the accumulation of freshly assimilated material in a leaf may, under favourable conditions, go on so rapidly as to give rise to a very appreciable increase of weight in the leaf lamina within the short space of a few hours. By observing at

[1] By far the most interesting and important result of Bokorny is the proof he gives that formaldehyde is directly assimilable by *Spirogyra*. His early attempts to show this had been rendered abortive by the highly poisonous nature of this substance. The difficulty was surmounted by using a dilute solution of sodium oxymethylsulphonate, which on warming with water splits up into formaldehyde and acid sodium sulphite. To prevent the unfavourable action of the acid sodium sulphite, dipotassium or disodium phosphate was added to the plant cultures. In such a solution, with rigid exclusion of carbon dioxide, *Spirogyra majuscula* forms starch in its chlorophyll bodies, but the access of light appears to be necessary.

The importance of this experiment is very great in connection with Baeyer's well-known hypothesis that the first act of assimilation is the reduction of carbon dioxide and water to the state of formaldehyde.

different times of the day the varying dry weight of equal areas of large leaves, Sachs obtained an approximate measure of the rate of the assimilatory process which he could express in terms of actual number of grams of substance assimilated by a unit area of leaf in unit of time. In this manner he was able to show, for instance, that a sunflower leaf, whilst still attached to the plant, increases in weight when exposed to bright sunshine at the hourly rate of about one gram per square metre of leaf area. In the case of similar leaves detached from the plant, and of course under conditions in which the products of assimilation were entirely accumulated in the leaf, he found an increase in weight of rather more than $1\frac{1}{2}$ grams per square metre per hour.

I was able to confirm this work of Sachs in the course of an investigation on the Chemistry of Leaves which I made with Dr. G. H. Morris in 1892–93, and there can be no doubt that the variations in the weight of leaves can be used as a fair index of the activity of a leaf in assimilating, but it is not a method which admits of much refinement of accuracy, owing, amongst other things, to the want of perfect symmetry in the leaves as regards thickness and density of the laminæ and to the possible migration of the assimilated material into the larger ribs, which of course cannot be included in the weighings.

It is evident that a far better plan of measuring the rate of assimilation under varying conditions would be the estimation of the actual amount of carbon dioxide entering a given area of the leaf in a certain time, and it was to the perfection of a method of this kind that Mr. Escombe and I first turned our attention.

In all previous attempts to measure the rate of ingress of carbon dioxide, such as those of Corenwinder, and more recently still of Mr. F. F. Blackman, it has been necessary to use air containing comparatively large quantities of carbon dioxide, amounting to 4 per cent. and upwards. Interesting and useful as such experiments undoubtedly are from the point of view from which they were undertaken, we must not lose sight of the fact that such conditions are highly artificial, and very far removed from those under which a plant finds itself in the natural state, where its leaves are bathed with air containing, not 4 or 5 per cent., but only ·03 per cent. of carbon dioxide. I shall have occasion later on to show how remarkably the rate of intake of carbon dioxide into a plant is influenced by extremely small variations in the tension of that gas, and that on this account no deduction can be drawn as to the rate of assimilation under natural conditions from any experiments in which the air contains even so small an amount of carbon dioxide as 1 per cent.

Before proceeding further in this direction, however, it will be well to consider the amount of carbon dioxide which must enter a leaf in a given time in order to produce an influence on its weight comparable with that indicated by the Sachs method of weighing definite areas For this purpose I will consider a leaf with which we have made many experiments—that of *Catalpa bignonioides*. It is a very symmetrical leaf and a good assimilator, and since the intake of carbon dioxide takes place only on the under side, the question to which I wish to draw your attention can be stated in a simple manner. When such a leaf is subjected to a modified form of the half-leaf weighing method of Sachs, into the details of which I cannot here enter, it may, under favourable conditions, show an increase in dry weight equal to about one gram per square metre per hour. Since this increase in weight is due almost entirely to the formation of carbohydrates, we can calculate with a close approximation to accuracy the corresponding amount of carbon dioxide. This will of course depend, within certain narrow limits, on the nature of the carbohydrate formed. The formation of a gram of starch requires 1·628 grams of carbon dioxide, whilst an equal amount of a $C_6H_{12}O_6$ or a $C_{12}H_{22}O_{11}$ sugar require 1·466 and 1·543 grams respectively. From the knowledge we possess of the nature of the carbohydrates of the leaf, we are quite sure that the mean of these values, that is 1·545 grams, must be very near the truth. This amount corresponds to 784 c.c. of carbon dioxide at normal temperature and pressure, which must represent the volume abstracted by the square metre of leaf surface in one hour from air containing only three parts of carbon dioxide in 10,000, supposing the method of leaf weighing to give correct results. We shall see later on that this intake can be verified by direct estimations; it is equivalent to the total amount of carbon dioxide in a column of air of a cross section equal to that of the leaf, and of a height of 26 decimetres.

The extraordinary power which an assimilating leaf possesses of abstracting carbon dioxide from the air is best shown by comparing it with an equal area of a freely exposed solution of caustic alkali. We have made a very large number of experiments on the rate at which atmospheric carbon dioxide can be taken up by a solution of caustic soda under varying conditions, and have been surprised to find how constant the absorption is. In a moderately still air a square metre of surface of such a freely exposed solution will absorb about 1200 c.c. of carbon dioxide per hour, and this can only be increased to about 1500 c.c. even if the dish is exposed to the full influence of a strong wind out in the open. When the surface of the liquid is constantly renewed during the experiment by means of a mechanical stirrer, the rate of absorption is not sensibly affected, providing the agitation does not appreciably increase the surface area, and considerable variations in the strength of the alkaline solution are also without any effect. On the other hand, slight variations in the tension of the carbon dioxide of the air have a marked influence on the rate of absorption, and in order to study this point we have constructed an apparatus which allows us to pass over an absorptive surface of liquid a current of air in a stratum of known thickness, and with a known average velocity.

By introducing definite amounts of carbon dioxide into this stream of air we have been able to determine the influence of its tension on the rate of absorption. At present we have only employed air containing amounts varying from 0·8 to 13 parts per 10,000, that is to say, from about one-quarter to a little more than four times the amount contained in normal air. Within these limits, and probably beyond them, the rate of absorption by the alkaline surface is strictly proportional to the tension of the carbon dioxide in the air current. I shall have occasion to show later on that the same rule holds good with regard to an assimilating leaf, and that in this case also, within certain limits, the intake of the gas is proportional to its tension.

The fact which I wish more particularly to bring out in these comparisons is that a leaf surface which is assimilating at the rate of one gram of carbohydrate per square metre per hour is absorbing atmospheric carbon dioxide *more than half as fast as the same surface would do if wetted with a constantly renewed film of a strong solution of caustic alkali.*

From what I have just said about the influence of tension on the absorption of carbon dioxide by an assimilating leaf, it is clear that any attempts to determine by direct means the natural intake of that gas during assimilation must be made with *ordinary* air, and that such experiments can only be carried out on a comparatively large scale. We had in the first instance to devise an apparatus which would rapidly and completely absorb the whole of the carbon dioxide from a stream of air passing through it at the rate of from 100 to 200 litres per hour, and at the same time admit of an extremely accurate determination of the absorbed carbon dioxide.

The absorbing apparatus which we finally adopted is a modification of one used by Reiset in his estimations of the carbon dioxide of the atmosphere. It consists essentially of a glass tube 50 cm. long, fixed vertically in a wide-mouthed glass vessel furnished with a second aperture and tubulure. The height of the vertical tube is invariable, but its width is regulated according to the amount of air required to be drawn through the apparatus in a given time. The bottom of this tube is closed with a platinum or silver plate pierced with a large number of very small holes, and two other similar perforated plates are inserted in the tube at certain intervals. The upper part of the tube is put in connection with an aspirating water-pump, and the absorbing liquid is placed in the lower glass vessel, whose second tubulure is connected with the supply of air in which the carbon dioxide has to be determined. When the aspirator is started the liquid is first drawn up into the vertical tube, and the air then follows through the perforated plates which act as "scrubbers." Reiset, in his work, used baryta water as the absorbent, an aliquot part of which was titrated before and after the experiment, the changes in the volume of the liquid being corrected for by certain devices which I need not describe.

The efficiency of the apparatus as a complete absorber of atmospheric carbon dioxide leaves nothing to be desired, but in dealing with large quantities of baryta solution, amounting to 400 c.c. or more, the errors due to inaccurate titrations, or to over or under estimation of the volume changes, are all thrown on the final result, of which they may form a considerable part. We have consequently altogether discarded the use of baryta as an absorbent in favour of caustic soda. The carbonate is esti-

mated by a double titration process, suggested a few years ago by Hart, and we have succeeded in so far improving this method that there is no difficulty in determining in 100 c.c. of the alkaline solution an amount of carbonate corresponding to $\frac{1}{10}$ c.c. of carbon dioxide.

There is practically no limit to the amount of air which can be passed through an absorbing apparatus such as I have described, and one of very moderate dimensions will allow from 100 to 150 litres per hour to pass with perfect safety. Larger amounts can be dealt with either by increasing the size of the apparatus or by using several smaller ones arranged in parallel.

With proper precautions, determinations can certainly be made to within ·02 part of carbon dioxide in 10,000 of air, so that with an apparatus of this kind it is possible to estimate the intake of carbon dioxide into a leaf or plant from ordinary atmospheric air, and to keep a sufficiently rapid stream of air passing over the leaf to maintain the tension of the carbon dioxide only slightly below the normal amount.

The air is measured by carefully standardised meters, reading to about 20 c.c.; and since the amounts of air aspirated vary from 100 to 900 litres or more, there are practically no errors of measurement. The tension at which the air passes through the absorption apparatus is measured by a manometer, and all the volumes are reduced to standard temperature and pressure.

All such experiments of course necessitate, not only a determination of the carbon dioxide in the air which has passed over the leaf or plant, but also a simultaneous determination of the carbon dioxide in the ordinary air used. The accumulation of these air determinations clearly shows that the ordinary statements of our text-books as to the amount of carbon dioxide and its limits of variation are altogether misleading.

In our experiments the air was in all cases taken from a height of four feet six inches from the ground, the amounts aspirated varying from 100 to 500 litres.

In the month of July 1898, the minimum amount of carbon dioxide found was 2·71 parts per 10,000 of air, and the maximum 2·86. During the winter months, when the ground was almost bare of vegetation, it rose to from 3·00 to 3·23 parts per 10,000; and on one foggy day, March 16, 1899, after a whole week of similar weather, we found the very exceptional amount of 3·62. As a rule, we may take it that the amount of carbon dioxide in the atmosphere during the period of greatest plant growth rarely falls short of 2·7 parts per 10,000, and rarely exceeds 3·0 parts, with an average of about 2·85. These numbers come very close to the determinations of Reiset, and of Müntz and Aubin, and agree also fairly well with the Montsouris determinations.

If instead of taking the air from a height of three or four feet from the ground, we examine the stratum only one or two centimetres above the surface of a soil free from vegetation, we find, as might be expected, a very large increase in the amount of carbon dioxide, which may exceed, under these circumstances, 12 or 13 parts per 10,000 of air. Such a soil, in fact, gives off by diffusion into the surrounding air an amount of carbon dioxide which is comparable to that evolved by a respiring leaf, that is to say, about 50 c.c. per square metre per hour. This is probably a factor which has to be taken into account in considering the assimilative power of vegetation of very low growing habit, but in all other cases we may assume with safety that aërial plants have to take in their carbon dioxide from air in which its tension does not exceed $\frac{3}{10000}$ of an atmosphere.

The actual intake of carbon dioxide is determined by enclosing the entire leaf in specially constructed air-tight, glazed cases, through which a sufficiently rapid air stream is passed. These cases are so arranged tbat the leaf can be enclosed whilst still attached to a plant which is growing out in the open under perfectly natural conditions, and some of them are sufficiently large to take the entire leaf of a sunflower.

The carbon dioxide content of the air is determined both before and after its passage through the apparatus, and since the amount of air passed is known we have all the data requisite for determining the actual amount retained by the leaf.

An experiment generally lasts from five to six hours, and the carbon dioxide fixed in this time may amount to 150 c.c. or more, the actual error of determination being very small indeed.

For purposes of comparison the volumes are reduced to the actual number of cubic centimetres of the gas absorbed by a square metre of leaf in one hour, which of course necessitates an exact determination of the area of the leaf. This is most conveniently effected by printing the leaf on sensitised paper, and tracing round its outline with a planimeter set to read off square centimetres—a far more accurate and expeditious plan than that of cutting out a fac simile of the leaf from paper of a known weight per unit of area.

If it is desired to estimate the assimilative power of a leaf in an atmosphere artificially enriched with carbon dioxide, the air stream before entering the leaf case is passed through a small tower containing fragments of marble, over which there drops a very slow stream of dilute acid, whose rate of flow is so proportioned to the air stream as to give about the desired enrichment with carbon dioxide. The stream of air is then divided, one part going on directly to the leaf case, whilst the other passes through a separate absorption apparatus and meter for the accurate determination of its carbon dioxide content.

In order to show the kind of results obtained in this manner, I will give one or two examples.

A leaf of the sunflower, having an area of 617·5 sq. cm., was enclosed in its case whilst still attached to the plant, and was exposed to the strong diffuse light of a clouded sky for five and a half hours, air being passed over it at the rate of nearly 150 litres per hour. The content of the air in carbon dioxide as it entered the apparatus was 2·80 parts per 10,000, and this was reduced to 1·74 parts per 10,000 during its passage over the leaf. This corresponds to a total absorption of 139·95 c.c. of carbon dioxide, or to an intake of 412 c.c. per square metre per hour. If we assume that the average composition of the carbohydrates formed is that of a $C_6H_{12}O_6$ sugar, the above amount of carbon dioxide corresponds to the formation of 0·55 gram of carbohydrate per square metre per hour. But we must bear in mind that the average tension of the carbon dioxide in the leaf case was only equal to 1·93 parts per 10,000—that is, only about seven-tenths of its tension in the normal air. A correction has therefore to be made if we wish to know how much the leaf would have taken in, under similar conditions of insolation, if it had been bathed with a current of air of sufficient rapidity to practically keep the amount of carbon dioxide constant at its normal amount of 2·8 per 10,000. We shall see later on that, well within the limits of this experiment, the intake is proportional to the tension, so that applying this correction we may conclude that under identical conditions of insolation and temperature this leaf would have taken in an amount of carbon dioxide from the free air at a rate sufficient to produce 0·8 gram of carbohydrate per square metre per hour. This is almost exactly equal to the assimilation rate of the sunflower which I deduced in 1892 from the indirect process of weighing equal areas of the leaf lamina before and after insolation, and it also agrees fairly well with some of Sachs' original experiments of a similar nature.

In another experiment made with the leaf of *Catalpa bignonioides* in full sunlight, the amount of carbon dioxide in the air passing over the leaf fell from 2·80 to 1·79 parts per 10,000, the total hourly intake for the square metre being 344·8 c.c. When this is corrected for tension, it corresponds to an assimilation in free air of 0·55 gram of carbohydrate per square metre per hour.

An increase in the intensity of the daylight, as might be expected, influences to some extent the rate of intake of atmospheric carbon dioxide; but providing the illumination has reached a certain minimum amount, a further increase in the radiant energy incident on the leaf does not result in anything like a proportional amount of assimilation. We have found, for instance, that the rate of assimilation of a sunflower leaf, exposed to the clear northern sky on a warm summer's day, was about one-half of what it was when the leaf was turned round so as to receive the direct rays of the sun almost normal to its surface. Now in this latter case the actual radiant energy received by the leaf was at least twelve times greater than was received from the northern sky, but the assimilation was only doubled.

These differences in the effect of great variation of illumination become stil less marked when we use air which has been artificially enriched with carbon dioxide. In one instance of this kind, for example, we found the assimilation in the full diffuse light of the northern sky to be 87 per cent. of what it was in direct sunshine.

This brings me to another interesting point on which I have

already touched slightly—the enormous influence which slight changes in the carbon dioxide content of the air exert on the rate of its ingress into the assimilating leaf.

With a constant illumination, either in direct sunlight or diffuse light, the assimilatory process responds to the least variation in the carbon dioxide, and within certain limits, not yet clearly defined, the intake of that gas into the leaf follows the same rule as the one which holds good with regard to the absorption of carbon dioxide by a freely exposed surface of a solution of caustic alkali; that is to say, from air containing small but variable quantities of carbon dioxide *the intake is directly proportional to the tension of that gas.*

A single experiment will be sufficient to illustrate this.

A large sunflower leaf, still attached to the plant and exposed to a clear northern sky, gave an assimilation rate equal to 0·331 gram of carbohydrate per square metre per hour, when air was passed containing an average amount of 2·22 parts of carbon dioxide per 10,000. When the experiment was repeated under similar conditions of illumination, but with air containing 14·82 parts of $CO_2$ per 10,000, the intake corresponded to an hourly formation of 2·409 grams of carbohydrate per square metre. The ratio of the tensions of the carbon dioxide in the two experiments is 1 to 6·7, and the assimilatory ratio is 1 to 7·2, so that the increased assimilation is practically proportional to the increase in tension of the carbon dioxide.

Since an increase of carbon dioxide in the atmosphere surrounding a leaf is followed by increased assimilation even in diffuse daylight, it is clear that, under all ordinary conditions of illumination, the rays of the right degree of refrangibility for producing decomposition of carbon dioxide are largely in excess of the power of the leaf to utilise them. Under natural conditions this excess of radiant energy of the right wave-length must, from the point of view of the assimilatory process, be wasted, owing to the limitation imposed by the high degree of dilution of atmospheric carbon dioxide. But although the actual manufacture of new material within the leaf lamina is so largely influenced by small variations in the carbon dioxide of the air, we are not justified in concluding that the plant *as a whole* will necessarily respond to such changes in atmospheric environment, since the complex physiological changes involved in metabolism and growth may have become so intimately correlated that the perfect working of the mechanism of the entire plant may now only be possible in an atmosphere containing about three parts of carbon dioxide in 10,000.

We have commenced a series of experiments which will, I hope, throw considerable light on this point, but the work is not at present in a sufficiently advanced state for me to make more than a passing allusion to it.

The penetration of the highly diluted carbon dioxide of the atmosphere into the interior air-spaces of the leaf on its way to the active centres of assimilation must, in the first instance, be a purely physical process, and no explanation of this can be accepted which does not conform to the physical properties of the gases involved.

Since there is no mechanism in the leaf capable of producing an ebb and flow of gases within the air spaces of the mesophyll in any way comparable with the movements of the tidal air in the lungs of animals; and since also the arrangement of the stomatic openings is such as to effect a rapid equalisation of pressure within and without the leaf, we must search for the cause of the gaseous exchange, not in any mass movement, but in some form of diffusion. This may take place in the form of *open diffusion* through the minute stomatic apertures, which are in communication both with the outer air and the intercellular spaces, or the gaseous exchange may take place through the cuticle and epidermis by a process of *gaseous osmosis*, similar to that which Graham investigated in connection with certain colloid septa.

For many years there has been much controversy as to which form of gaseous diffusion is the more active in producing the natural interchanges of gases in the leaf. The present occasion is not one in which full justice can be done to the large amount of experimental work which has from time to time been carried out in this direction. Up to comparatively recently the theory of cuticular osmosis has been the one which has been more commonly accepted, free diffusion through the open stomata being considered quite subsidiary. In 1895, however, Mr. F. F. Blackman brought forward two remarkable papers which opened up an entirely new aspect of the subject. After showing the fallacy underlying certain experiments of Boussingault, which had been generally supposed to prove the osmotic theory of exchange, Mr. Blackman gave the results of his own experiments with a new and beautifully constructed apparatus, which enabled him to measure very minute quantities of carbon dioxide given off from small areas of the upper and under sides of a respiring leaf, and also to determine the relative intake of carbon dioxide by the two surfaces during assimilation in air artificially charged with that gas. The conclusions drawn are that respiratory egress, and assimilatory ingress of carbon dioxide, do not occur in the upper side of a leaf if this is devoid of stomatic openings, and that when these openings exist on both the upper and under sides the gaseous exchanges of both physiological processes are directly proportional to the number of stomata on equal areas, hence in all probability the exchanges take place only through the stomata.[1]

These observations of Mr. Blackman are of such far-reaching importance, and lead, as we shall see presently, to such remarkable conclusions with regard to the rate of diffusion of atmospheric carbon dioxide, that we felt constrained to inquire into the matter further, and for this purpose we employed a modified form of the apparatus which we have used throughout our work on assimilation. This was so arranged that a current of ordinary air could be passed, just as in Mr. Blackman's experiments, over the upper and lower surface of a leaf separately, the increase or decrease in the carbon dioxide content of the air being determined by absorption and titration in the manner I have already alluded to.

In this way we were able to employ comparatively large leaf areas, and to continue an experiment for several hours, so that we had relatively large amounts of carbon dioxide to deal with, and the ratios of gaseous exchange of the two sides of the leaf could consequently be determined with considerable accuracy.

Our results, on the whole, are decidedly confirmatory of Mr. Blackman's observations. The side of a leaf which is devoid of stomatic openings certainly neither allows any carbon dioxide to escape during respiration, nor does it permit the ingress of that gas when the conditions are favourable for assimilation. On the other hand, when stomata exists on both the upper and under sides of a leaf, gaseous exchanges take place through both surfaces, and, as a rule, in some sort of rough proportion to the distribution of the openings. There is, however, under strong illumination, a greater intake of carbon dioxide through the upper surface than would be expected from a mere consideration of the ratio of distribution of the stomata.[2] Nevertheless, the general connection between gaseous exchange and distribution of stomata is so well brought out that we must regard it as highly probable that these minute openings are the true paths by which the carbon dioxide enters and leaves the leaf.

We must now look at certain physical consequences which proceed from this assumption, and see how far they can be justified by the known or ascertainable properties of carbon dioxide at very low tensions.

The leaf of *Catalpa bignonioides* is hypostomatic, and therefore takes in carbon dioxide only by its lower surface. Under

[1] There is one important fact to be borne in mind when considering how far these observations exclude the possibility of cuticular osmosis. In the many leaves we have examined, Mr. Escombe and I have found that the occurrence of stomata on the upper surface of the leaf is always correlated with a much less dense palisade parenchyma. The cuticle and epidermis under these conditions are in a much more favourable state to allow carbon dioxide to pass into the leaf by osmosis than when the closely-packed palisade-cells abut against the epidermis, as they do when this is imperforate.

[2] Granted that the stomata constitute the paths of gaseous exchange, it is clear that the amount of diffusion through them, other things being equal, must depend very largely on the extent to which they are opened. The delicate self-regulating apparatus which governs the size of the openings is so readily influenced, amongst other things, by differences of illumination, that *a priori* we should not expect the stomata on the upper surface of an insolated leaf to be in the same condition as those of the more shaded lower surface. This may very well account for the stomatic ratio of the two sides not being in closer correspondence with the assimilatory ratios, as found in most of our experiments carried out in bright sunlight. In light of lesser intensity there is always a closer correspondence of the two ratios.

There is also another possible explanation of the fact. Since we have good reason to believe that the principal part of the assimilatory work is carried on by the palisade parenchyma, which occurs in the upper side of the leaf, the tension of the carbon dioxide in the air spaces of that part of the mesophyll is probably less than it is in the spongy parenchyma. There will, therefore, be a higher "diffusion gradient" between the carbon dioxide of the outer and inner air in the former case than in the latter, and this would certainly tend to a more rapid diffusion through the openings in the upper side of the leaf.

favourable conditions it is quite possible, during assimilation, to obtain an intake of atmospheric carbon dioxide into this leaf at the rate of 700 c.c. per square metre per hour (measured at 0° and 760 mm.), corresponding to an average linear velocity of the carbon dioxide molecules of 3·8 *centimetres per minute*, supposing the intake to be distributed evenly over the whole of the lower leaf surface. This velocity is almost exactly one-half of that at which carbon dioxide will enter a freely exposed surface of a solution of caustic alkali. But if the intake of the gas is confined to the stomatic openings of the leaf, its velocity of ingress must be very much greater than this.

We have carefully determined the number of stomata occurring on a given area of this particular leaf, and also the dimensions of the openings, and find that the total area of the openings, supposing them to be dilated to the fullest possible extent, amounts to just under *one per cent.* of the leaf surface. It follows from this that the average velocity of the atmospheric carbon dioxide in passing through these openings must be 380 *centimetres per minute*, that is to say, just *fifty* times greater than into a freely exposed absorbent surface of alkali. In other words, supposing every one of the stomatic openings of this leaf could be filled up with a solution of caustic alkali, the absorbent power of the leaf as a whole would only be $\frac{1}{50}$ of what it actually is when assimilating.

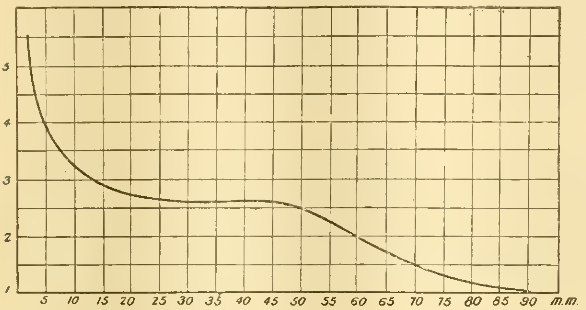

FIG. 1.

These are some of the consequences which flow from an acceptance of the hypothesis of stomatic exchange, and it appeared to be impossible to accept that hypothesis unreservedly without some collateral evidence that these comparatively high velocities of diffusion are physically possible when dealing with such low gradients of tension as must necessarily exist when the highest amount of carbon dioxide does not exceed ·03 per cent.

The well-known general law expressing the rate of the spontaneous intermixture of two gases when there is no intervening septum was, as every one knows, established by Graham, and the more elaborate investigations of Loschmidt many years later served to confirm the general accuracy of this law, and to show that, within very narrow limits, the diffusion constant varies in different gases inversely as the square roots of their densities.

But a mere knowledge of the diffusion constants of air and carbon dioxide does not, as far as I can see, materially assist us in the particular case we have under consideration. In order to gain some idea of what is actually possible in the way of stomatic diffusion in an assimilating leaf, we must know something of the *actual rate* at which atmospheric carbon dioxide can be made to pass into a small chamber containing air at the outside tension, but in which the carbon dioxide is kept down almost to the vanishing point by some rapid process of absorption; and we must also determine the influence of varying the size of the aperture through which the diffusion takes place.

Our attempts to answer these questions experimentally have led us into a long investigation, which promises to be of wider interest than we had first imagined. I only propose to give on this occasion a general account of the results so far as they affect the physical question of the intake of carbon dioxide into the plant.

When a shallow vessel containing a solution of caustic alkali is completely covered, the air above the liquid is very speedily deprived of the whole of its carbon dioxide. If we now imagine a hole to be made in the cover of the vessel, carbon dioxide will enter the air space by free diffusion, and its amount can be very accurately determined by subsequent titration in the manner I have previously referred to. The time occupied by the experiment and the dimensions of the aperture being known, we can express the results in actual amounts of carbon dioxide passing through unit area of aperture in unit of time; or, since the tension of that gas in the outer air is known, we can express the average rate of the carbon dioxide molecules across the aperture in terms of actual measurement, say centimetres per minute.

We have made a very large number of experiments of this kind, using, in the first instance, dishes of about 9 cm. in diameter, and varying the size of the holes in the cover, the air space over the absorbent liquid being always the same.

The accompanying curve, Fig. 1, illustrates the effect which a gradually decreasing orifice has on the rate of diffusion of atmospheric carbon dioxide under these conditions. The diameters of the orifice in millimetres are given on the abscissa line, and the rates of diffusion through equal areas of the apertures are taken as ordinates, the rate of absorption in the open dish under similar conditions being taken as unity.

It will be seen that in the first instance a gradual reduction of the diameter of the opening is accompanied by a very regular increase in the rate of passage of the carbon dioxide until a diameter of about 50 mm. is reached; that is to say, up to a point at which about two-thirds of the area of the dish is covered. A further progressive diminution in the size of the aperture makes comparatively little difference in the diffusion rate until we reach about 20 mm., beyond which the curve again begins to rise, increasing rapidly in steepness as the apertures become smaller.

The experiments with open dishes are too crude for a study of the influence of very small apertures, so for this part of our work we constructed a special form of apparatus which has enabled us to determine the relative rates of diffusion through orifices in thin metal plates ranging down to 1 mm. in diameter.

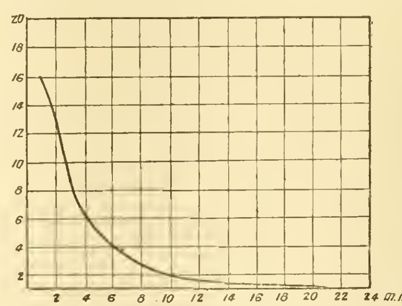

FIG. 2.

I have plotted the results of such a series of experiments (see Fig. 2), showing the relative rates of diffusion of atmospheric carbon dioxide through equal areas of apertures between 20 mm. and 1 mm. in diameter, under constant conditions, and it will be noticed how very steep the curve becomes after diameters of 5 or 6 mm. are reached.

The speed at which the diffusion of atmospheric carbon dioxide takes place through unit area of an orifice of 1 mm. in diameter is just sixteen times as fast as it is through unit area of an aperture of 20 mm.; and since we know that the rate of passage in the latter case is two and a half times greater than

the absorption rate of an equal area of a freely exposed surface of a solution of caustic alkali, we arrive at the conclusion that, under the particular conditions of our experiment, the diffusion rate through an aperture of 1 mm. is *forty times* greater than the rate of absorption of a free alkaline surface of equal area.

This corresponds to an actual average rate of passage of the molecules of the atmospheric carbon dioxide of about 266 centimetres per minute.

Now, we have already seen, in the case of a Catalpa leaf, that if the gaseous exchange during assimilation goes on only through the stomatic openings, we require a minimum velocity of something like 380 centimetres per minute, a velocity which we are sensibly approaching in our experiments with apertures of about 1 mm. in diameter. But the effective area of a stomatic opening of the Catalpa leaf is equal to that of a circle with a diameter of less than 1/100 mm., and since our experiments indicate a very rapid increase in the velocity of diffusion as the aperture is diminished, it is clear that no difficulty, as regards the physics of the question, can be raised against the idea that atmospheric carbon dioxide reaches the active centres of assimilation by a process of free diffusion through the leaf stomata.

One of the most interesting problems connected with plant assimilation relates to the efficiency of a green leaf as an absorber and transformer of the radiant energy incident upon it.

It is already well known that the actual amount of energy stored up in the products of assimilation bears a very small proportion to the total amount reaching the leaf: in other words, the leaf, regarded from a thermo-dynamic point of view, is a machine with a very low "economic coefficient." We require, however, to know much more than this, and to ascertain, amongst other things, how the efficiency of the machine varies under different conditions of insolation, and in atmospheres containing varying amounts of carbon dioxide.

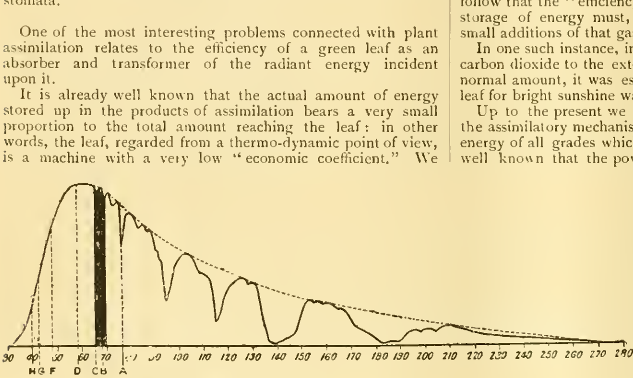

FIG. 3.

The measure of the two principal forms of work done within the leaf, the vaporisation of the transpiration water on the one hand, and the reduction of carbon dioxide and water to the form of carbohydrates on the other, can be ascertained by modifying our experiments in such a manner as to allow the transpiration water to be determined, as well as the intake of carbon dioxide.

For the actual measurement of the total energy incident on the leaf under various conditions we are now using one of Prof. Callendar's recording radiometers of specially delicate construction, which will be ultimately calibrated in calories. This instrument gives promise of excellent results, but up to the present time the work we have done with it is not sufficiently advanced for me to describe. We may, however, obtain a very fair idea of the variation in the efficiency of a leaf from one or two examples in which the amount of incident energy was deduced from other considerations.

In the case of a sunflower leaf exposed to the strong sunlight of a brilliant day in August, the average amount of radiant energy falling on the leaf during the five hours occupied by the experiment was estimated at 600,000 calories per square metre per hour. The averege hourly transpiration of water during that time was at the rate of 275 c c. per square metre, and the assimilated carbohydrate, estimated by the intake of carbon dioxide, was at the rate of 0·8 gram per square metre per hour.

The vaporisation of 275 c.c. of water must have required the expenditure of 166,800 calories, and the endothermic production of 0·8 gram of carbohydrate (taking the heat of combustion at 4000 gram calories) corresponds to the absorption of 3200 calories. Thus, as the final result under these particular conditions of experiment, we find that the leaf has absorbed and converted into internal work about 28 per cent. of the total radiant energy incident on it, 27·5 per cent. being used up in the vaporisation of water, and only *one-half per cent.* in the actual work of assimilation.

In strong diffuse light, such as that from a northern sky on a clear summer's day, the leaf has a higher "economic coefficient," using that term in relation to the permanent storage of energy in the assimilatory products. In one instance of this kind in which the total energy received by the leaf was approximately 60,000 calories per square metre per hour, it was found that 96 c.c. of water were evaporated and 0·41 gram of carbohydrate was formed for the same area and time. This indicates an absorption and utilisation by the leaf of something like 95 per cent. of the incident energy, of which 2·7 per cent has been made use of for actual work of assimilation as against 0·5 per cent. in brilliant sunshine.[1]

From what I have said previously about the effect of increased tension of carbon dioxide on the rate of assimilation, it must follow that the "efficiency" of a leaf as regards the permanent storage of energy must, *caeteris paribus*, be increased when small additions of that gas are made to the surrounding air.

In one such instance, in which the air had been enriched with carbon dioxide to the extent of about five-and-a-half times the normal amount, it was estimated that the "efficiency" of the leaf for bright sunshine was raised from 0·5 to 2·0 per cent.

Up to the present we have been regarding the efficiency of the assimilatory mechanism of a plant in reference to the *total* energy of all grades which falls upon the leaf. It is, of course, well known that the power of decomposing carbon dioxide is limited to rays of a certain refrangibility, and the researches of Timiriazeff, Engelmann and others leave little room to doubt that the rays of the spectrum which are instrumental in producing the reaction in the chloroplastids have a distinct relation to the absorption bands of the leaf-chlorophyll. By far the greater amount of the assimilatory work, probably more than 90 per cent. of it, is effected by the rays which correspond to the principal absorption band in the red, lying between wave-lengths 6500 and 6975.[2] If, therefore, we express the distribution of energy in a normal solar spectrum in the form of a curve, we have the means of approximately determining the *maximum theoretical efficiency* of a green leaf, that is to say, the maximum amount of assimilatory work which could be produced, supposing the conditions so favourable as to admit of the whole of the energy corresponding to this absorption band being stored up within the leaf.

It is not without interest to get an approximate idea of this theoretical maximum.

For this purpose I have here reproduced a curve given by Prof. S. P. Langley representing the distribution of energy at the sea-level in the normal spectrum of a vertical sun shining in

[1] The principal factor which determines the amount of transpiration in a plant must be the amount of radiation falling on it. It is essential that the water-bearing mechanism should be able to keep up a good supply of water to the leaf lamina in order to prevent the temperature rising to a dangerously high point. This "safety valve" function of the transpiration current is not always sufficiently borne in mind, and we are too apt to think that the plant requires these enormous amounts of water in order to supply itself with the requisite mineral salts. The absolute necessity for the supply as a dissipator of energy will become evident by taking one or two facts into consideration. A square metre of the lamina of the leaf of a sunflower weighs about 250 grams, and its specific heat is about 0·9. We have seen that the hourly transpiration in bright sunshine may be as much as 275 c.c. per square metre, requiring the expenditure of 162,800 calories, and it therefore follows that, if the loss of water were stopped, the temperature of the leaf would rise at the rate of more than 12° C. *per minute*. In making our experiments in glazed cases it has sometimes been very interesting to watch the result of any accidental stoppage of the water-current in the leaf-stalk, and the almost instantaneous effect this has in destroying the leaf when the insolation is of high intensity.

[2] These limits are those of the band as measured by passing sunlight through the leaf itself. In an alcoholic solution of chlorophyll the band lies between λ 6400 and λ 6850. I must here express my thanks to Mr. Charles A. Schunck for having kindly undertaken to make these measurements for me.

a clear sky. The total amount of incident energy represented by the whole area of the curve is 1·7 calories per square centimetre per minute, or 1,020,000 calories per square metre per hour.

I have drawn a thick black vertical band in the red end of the spectrum corresponding in position and breadth with the principal absorption band of chlorophyll as seen in a green leaf. By integration it may be shown that the area of this part of the curve is about 6·5 per cent. of that of the whole curve, so that this value represents something like the theoretical maximum efficiency of a leaf in bright vertical sunshine, supposing the conditions could be made so favourable as to result in a complete filtering-out and utilisation of the whole of the rays of the right period for producing decomposition of carbon dioxide.

This maximum efficiency expressed in calories per square metre per hour is 66,300, corresponding to the heat of formation of about 16·5 grams of carbohydrate. Under the most favourable conditions we have employed up to the present we have not obtained a larger production than about 3·0 grams of carbohydrate per square metre per hour, or about 18 per cent. of the theoretical maximum; but this was in air containing only 16·4 parts of carbon dioxide per 10,000, which must be very far below the true optimum amount.

The brilliant discoveries of recent years on the constitution and synthesis of the carbohydrates have not brought us sensibly nearer to an explanation of the first processes of the reduction of carbon dioxide in the living plant. The hypothesis of Baeyer still occupies the position it did when it was first put forward nearly thirty years ago, although it has, it is true, received a certain amount of support from the observations of Bokorny, who found that formaldehyde can, under certain conditions, contribute to the building up of carbohydrates in the chloroplasts.

The changes which go on in the living cell are so rapid, and are of such a complex kind, that there seems little or no hope of ascertaining the nature of the first steps in the process unless we can artificially induce them under much simpler conditions.

The analogy which exists between the action of chlorophyll in the living plant and that of a *chromatic sensitiser* in a photographic plate, was, I believe, first pointed out by Captain Abney, and was more fully elaborated by Timiriazeff, who was inclined to regard chlorophyll as the sensitiser *par excellence*, since it absorbs and utilises for the assimilatory process the radiations corresponding approximately to the point of maximum energy in the normal spectrum. The view which Timiriazeff has put forward, that there is a mere physical transference of vibrations of the right period from the absorbing chlorophyll to the reacting carbon dioxide and water, is, I think, far too simple an explanation of the facts. Chromatic sensitisers have been shown to act by reason of their antecedent decomposition and not by direct transference of energy, and the same probably holds good with regard to chlorophyll, which is also decomposed by the rays which it absorbs. We must probably seek for the first and simplest stages of the assimilatory process in the interaction of the reduced constituents of the chlorophyll and the elements of carbon dioxide and water, the combinations so formed being again split up in another direction by access of energy from without.

The failure of all attempts to produce such a reaction under artificial conditions is, I think, to be accounted for by the neglect of one very important factor. We are dealing with a reaction of a highly endothermic nature, which is probably also highly *reversible*, and on this account we cannot expect any sensible accumulation of the products of change unless we employ some means for removing them from the sphere of action as fast as they are formed.

In the plant this removal is provided for by the living elements of the cell, by the chloroplast, assisted no doubt by the whole of the cytoplasm. We have here, in fact, the analogue of the *chemical sensitisers* of a photographic plate, which act as halogen absorbers, and so permit a sensible accumulation of effect on the silver salts.

When we have succeeded in finding some simple chemical means of fixing the initial products of the reduction of carbon dioxide, then, and then only, may we hopefully look forward to reproducing in the laboratory the first stages of the great synthetic process of nature on which the continuance of all life depends.

## *NOTES.*

THE Allahabad *Pioneer Mail* understands that Mr. J. N. Tata, of Bombay, has determined to dissociate his offered endowment for a scientific research institute in India from the proposed family settlement, which was one of the original conditions, as the latter part of the scheme presented insuperable difficulties. With great generosity and public spirit Mr. Tata has declared his intention of making his offer, which amounts, it will be remembered, to some thirty lakhs of property, quite unconditional. He is now preparing, in consultation with the provisional committee, a revised scheme for submission to Government. In preparing it, he and the provisional committee will utilise all the information and advice they have received from all parts of India in response to the circulars issued some months ago, and there is good prospect of a practical plan being evolved.

THE forty-eighth annual meeting of the American Association for the Advancement of Science was held at Columbus, Ohio, on August 19–26, under the presidency of Dr. Edward Orton, of Ohio State University. There were 350 members and associates present, and 273 papers were communicated to the sections. The address of the retiring president, Prof. F. W. Putnam, of Harvard University, was published in last week's NATURE, and portions of the addresses delivered by presidents of the sections will appear at the earliest opportunity. The subjects of these addresses are:—Section of Mathematics and Astronomy, "The Fundamental Principles of Algebra," by Prof. A. Macfarlane; Section of Mechanical Science and Engineering, "Engineering Education as a Preliminary Training for Scientific Research Work," by Prof. Storm Bull; Section of Zoology, "The Importance and the Promise in the Study of the Domestic Animals," by Prof. Gage; Section of Geology and Geography, "The Devonian in Canada," by Mr. J. F. Whiteaves; Section of Physics, "The Field of Experimental Research," by Dr. Elihu Thomson; Section of Chemistry, "Definition of the Element," by Prof. F. P. Venable; Section of Botany, "The Progress and Problems of Plant Physiology," by Prof. Barnes; Section of Anthropology, "Beginnings of the Science of Prehistoric Anthropology," by Prof. Wilson. Prof. C. E. Munroe delivered a popular lecture on "Applications of Modern Electricity." New York was selected as the place of meeting next year, and Prof. R. S. Woodward, Columbia University, was nominated president.

A VERY successful congress of mining engineers was held at Teplitz, in Bohemia, on September 4–8. It was attended by 400 mining engineers from all parts of Austria and by a few representatives of other countries, Great Britain being represented by Mr. H. Bauerman, Mr. Bennett Brough and Mr. D. A. Louis. Mr. Gottfried Hüttemann, of Brüx, was elected president; Mr. J. Gleich, of Klagenfurt, and Prof. Clemens Winkler, of Freiberg, vice-presidents; and Prof. J. von Ehrenwerth, of the Przibram School of Mines, and Mr. M. Heinsius, secretaries. Papers were read by Prof. Clemens Winkler, on the history of combustion with reference to the duration of the world's coal supply; by Prof. Otto Frankl, of Prague, on suggested reforms in mining law; by Mr. H. Löcker, of Brüx, on water-inbursts in the Dux-Ossegg collieries and their influence on the Teplitz hot-springs; and by Mr. A. Bloemendal, of Vienna, on the electric transmission of power in mines. It was decided that the next mining congress should be held in Vienna in four years' time. In connection with the congress, excursions were arranged to the brown coal mines of the Brüx Coal Co. and of the Bruch Coal Co., to the Teplitz rolling mills, to the Aussig chemical works, to Edmundsklamm and other points of geological interest in the Bohemian Switzerland, and to the

Kladno collieries. The importance of the brown coal mines of the Teplitz district is shown by the fact that last year they produced no less than 15,044,563 tons, and afforded employment to 25,212 workmen.

THE reports which the *Times* correspondent at St. Johns has received from the members of the Peary Polar expedition, who have returned in the steamer *Windward*, are disappointing. Grinnell Land was explored to its western extremity last autumn; the north remains to be explored. Next spring, Lieut. Peary will undertake the three years' further prosecution of his quest for the pole. Captain Sverdrup, in the *Fram*, wintered fifty miles south of the *Windward*, in latitude 79°. The work of the expedition has so far been unimportant.

THE Danish Greenland expedition, under Lieut. Amstrup, has returned to Mandal, after a year's absence, and reports that no trace was found of Herr Andrée and his companions. A Reuter telegram states that the Swedish search expedition under Dr. Nathorst, which has just arrived at Malmo, brings a similar report. The expedition explored Kaiser Franz Joseph Fiord, on the east coast of Greenland, and there discovered a whole series of new inlets, the position of which was mapped. An especially interesting ethnographical collection relating to the now extinct Eskimo population was secured in that region.

THE forty-fourth annual exhibition of the Royal Photographic Society, which will be held at the Gallery of the Royal Society of Painters in Water Colours, is now in course of preparation, and will be opened to the public on Monday, September 25, for a period of seven weeks. On Saturday, the 23rd, there will be a private view for members, exhibitors, and their friends, and in the evening there will be a conversazione, when the President, the Earl of Crawford, K.T., will receive the members and the other guests of the Society.

A CONGRESS of the Royal Institute of Public Health will be held at Blackpool on September 21-28.

A COURSE of twelve free lectures on the "Pleistocene Mammalia" will be delivered by Dr. R. H. Traquair, F.R.S., in the Lecture Theatre of the Museum of Practical Geology, Jermyn Street, S.W., on Mondays, Wednesdays and Fridays, at 5 p.m., beginning Monday, October 2, and ending Friday, October 27.

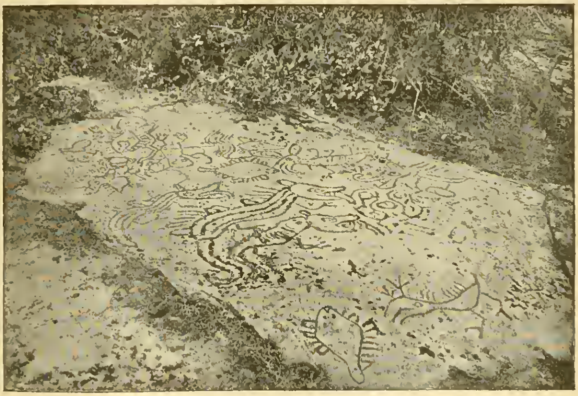
THE committee appointed by the American Chemical Society to consider the means by which the Society could hasten the adoption of uniform systems of graduation, definite limits of accuracy, and standard methods for using all forms of measuring instruments employed in chemical laboratories have, we learn from *Science*, made the following recommendations:—(1) That the American Chemical Society, in a manner consistent with its constitution and bye-laws, ask the U.S. Office of Weights and Measures to adopt regulations for the verification of volumetric apparatus which shall be similar in purpose and scope to the regulations of the Kaiserliche Normal-Aichungs-Commission, after due consideration of the criticisms to which the latter have been subjected. (2) That the U.S. Office of Weights and Measures be asked to give special consideration to the question of a standard temperature or temperatures to be adopted for the graduation of volumetric apparatus, and to obtain as far as practicable an expression of opinion from American chemists on this point. (3) That the U.S. Office of Weights and Measures be asked to submit its regulations to the American Chemical Society, or a duly appointed committee thereof, for suggestions before final adoption by that office. (4) That the international kilogram be adopted as the standard mass. (5) That the litre as defined by the International Committee on Weights and Measures be adopted; viz. the volume of the *mass* of a kilogram of pure water at the temperature of maximum density and under a pressure of 760 mm. of mercury. (6) That all density determinations be referred to water at its maximum density and under a pressure of 760 mm. of mercury. (7) That all temperatures be expressed in terms of the hydrogen thermometer of the International Bureau of Weights and Measures. (8) That if any question arise as to the interpretation of the above definitions the decision and standards of the U.S. Office of Standard Weights and Measures shall be accepted by the Society as final.

THE Rev. J. M. Bacon contributes to *Good Words* a general account of his experiments on the audibility of sound in air. It is well known that the report of the explosion of a large meteor may be heard over a great area, although the air at the point where the explosion occurs must be extremely attenuated. Mr. Bacon has endeavoured to imitate the meteoritic explosions to some extent by electrically firing Tonite cartridges suspended below a balloon. An ascent was made, and cartridges were fired at intervals, the altitude of the balloon ranging from 2000 to 3000 feet. The reports were heard by many observers in the parts of London over which the balloon passed, and some interesting conclusions were derived from these observations. In the balloon itself careful readings were taken of the interval of the return of the echo from the earth, and the height the balloon had ascended, while the actual locality over which each cartridge was fired was also noted. From the results obtained, it appeared that there were no aërial echoes, as in Prof. Tyndall's experiments, and that in all cases the reports in their double journey did not travel as quickly as the estimated speed of sound on the earth. "In consequence of these unexpected records," says Mr. Bacon, "another ascent was carried out shortly afterwards from the Crystal Palace when the air was in a totally different condition, and the altitude reached considerably higher. On that day a strange thing happened. The afternoon was an universal drizzle, and the Palace towers had their heads nearly shrouded in the low-lying clouds. On rising the balloon at once made for the west, and entering the cloud shortly reappeared above in glorious sunshine. So for nearly two hours, when, once again descending through the clouds, we found ourselves still going west, but dead over the middle of the river below the fort at Gravesend! All unsuspected by the voyagers, a wind was blowing above the cloud-layer diametrically opposite to that on earth, but causing no impediment to sound thereby. The actual results obtained on the last occasion entirely confirmed those of the former experiment, and differed only in the fact that the reports were apparently heard over a much larger range of country, extending well into the neighbouring counties, and that the reverberations following them, as heard from above, were yet more prolonged than before, sometimes indeed still lingering on after an interval of thirty seconds."

THE Danish Meteorological Office has just published a valuable excerpt paper from its *Aarbog*, giving the meteorological means and extremes for the Faroe, Iceland and Greenland. At Thorshavn (Faroe) the mean monthly values of air temperature during twenty-five years vary from 37°·8 in January and March to 51°·4 in July. The absolute maximum was 70°·2, and the minimum 11°·1. The mean annual rainfall was 63·3 inches, and the greatest fall in twenty-four hours 2·5 inches. For Iceland mean temperature values are given for nineteen years at fifteen stations; the lowest yearly mean is 30°·6 at Moedrudal, and the highest, 41°·0 at Vestmannœ. At Stykkisholm the absolute maximum during twenty-two years was 73°·2 in July, and the minimum – 14°·8 in January. The mean annual rainfall was 24·9 inches, and the greatest fall in twenty-four hours 2·04 inches. For Greenland four stations are given; at the most northern

station, Upernivik, latitude 72°·47, longitude 55°·53 W., the mean temperature of twenty-one years was 16°·2, absolute maximum 64·0, minimum −41°·1. The average rainfall was only 8·9 inches, and the greatest fall in twenty-four hours 2·08 inches.

THE report of the president of the American Museum of Natural History, on the work done during 1898, is a very satisfactory statement of scientific progress, especially the parts of it referring to archæological work and explorations made in connection with the museum. The institution now offers to the student of Mexican and Central American archæology unrivalled opportunities for the study of the sculptures and hieroglyphic writings of the ancient peoples of these portions of America. Noteworthy among the numerous explorations referred to in the report is the Jesup North Pacific Expedition. Before the organisation of this expedition the archæological work conducted on the north-west coast of America was very limited. During the past two years several field parties have carried on very extensive investigations in connection with the Jesup expedition, and have added very considerably to the collections in the museum. During 1897 the field work of the expedition was confined to the coast of British Columbia. In 1898 the work was taken up on a more extended scale. Parties were in the field on the coast of the State of Washington, in the southern interior of British Columbia, and on the Amoor River in Siberia. One of the illustrations in the report, showing a rock carving found in Vancouver Island, where the shell-heaps of the early inhabitants are being investigated, is here reproduced.



Rock carving, Vancouver Island.

ON July 19, for the fifth time during the present century, the city of Rome was damaged by an earthquake. On this last occasion, however, the injuries to buildings were of slight importance, the intensity of the shock having been greaest at Frascati and Marino. Dr. Baratta, who gives a brief description of the earthquake in the *Bollettino* of the Italian Geographical Society, remarks that, in its small meizoseismal area, it resembled the shocks which are characteristic of active and extinct volcanic regions, that it was without doubt of Latian origin, and one of the more prominent manifestations of seismic activity in the Alban Hills.

ONE result of the rapid growth of seismology is the suggestion by Dr. Mario Baratta that provision should be made by insurance against the damage to buildings caused by earthquakes in certain countries. He shows that, since the beginning of the seventeenth century, less than forty earthquakes have been responsible for the deaths of more than 150,000 persons in Italy alone. Moreover, to take but one example, the great loss of life during the Ischian earthquake of 1883 was due to the fact that the buildings had already been damaged by the earthquakes of 1828 and 1881. Dr. Baratta points out some of the conditions that must determine the amount of the premium that should be demanded by insurance societies. The most important is the degree of seismicity of the district; but this would be modified by others, such as the nature of the surface-rocks, the character of the buildings, &c. One advantage of compulsory insurance against earthquakes in a country like Italy would be that partially damaged buildings would be at once rebuilt or repaired, and this would tend to diminish the loss of life in the future.

THE Kew *Bulletin of Miscellaneous Information*, Nos. 152–153, contains the description of a new parasitic disease of the tea-plant which has made its appearance in Ceylon. The fungus which causes it is described by Mr. G. Massee as *Colletotrichum camelliæ*, sp. n.

CONSIDERABLY the most gigantic annual plant ever observed is described by Mr. C. H. Baker in the Kew *Bulletin*. The species in question is *Acnida australis*, belonging to the Amarantaceæ, a native of Florida. The branches attain certainly a length of nearly 22, and probably of 25, feet.

HYBRIDS between plants belonging to different genera are so uncommon that any fresh instance deserves a record. The *Journal of Botany* states that Mr. H. Peirson has found in Kent several examples of an orchid which appears to be a cross betweeen *Orchis maculata* and *Gymnadenia conopsea*.

A BRIEF summary of the changes which have taken place on Vesuvius from 1872 up to June 1899 is given by Dr. R. V. Matteucci in the *Rendiconto* of the Naples Academy, vol. 6, 7.

MR. A. A. CAMPBELL SWINTON sends us a reprint of his lecture read before the Philosophical Society of Glasgow in March last, on "Electric Discharges *in vacuo* and the Rontgen Rays."

THE Institution of Chemistry of Great Britain and Ireland has issued, in the form of a handy octavo pamphlet, its regulations for admission to membership, together with a register of fellows, associates and students for the session 1899–1900, and reprints of examination papers set in the session 1898–99.

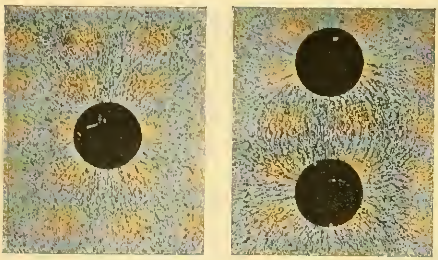
A DETERMINATION of the modulus of elasticity for copper, brass, and steel under small loads by means of interference methods is described by Mr. Charles P. Weston in the *Physical Review* viii. 5, and leads to the important conclusion that for copper and brass, and probably for steel, the ratio between the deflection and a load is a constant quantity for loads ranging from 0·5 gr. to those which would give the bar a permanent set.

DR. AGOSTINO GALDIERI, writing in the *Rendiconto* of the Naples Academy, vol. 6, 7, describes a new alga of the family Palmellaceæ, to which he has given the name *Pleurococcus sulphurarius*, and which he has discovered growing round the

"fumaroli" of the Solfatara at Pozzuoli. This alga is characterised by its remarkable resistance to heat and to the action of sulphuric acid.

MR. WILLIAM FOSTER, jun., writes in the *Physical Review*, viii. 5, on the conductivity and dissociation of some electrolytes, and confirms the values of the depressions of the freezing point as determined by Loomis, within as narrow limits as one should expect. The results also, with a few minor exceptions, conform to the dissociation theory as set forth by Arrhenius, and the author considers that in the present state of physical chemistry we are compelled to look upon this theory as the one that most nearly corresponds with the experimental data, thus affording, at least, a working hypothesis by which the most important generalisations can be made.

To impress upon students the identity of the laws of force for magnetism and electricity at rest, it is necessary to obtain pictures of electrostatic curves analogous to those shown around magnets by means of iron filings. Mr. David Robertson describes in the *Proceedings* of the Royal Society of Edinburgh the way in which such dust figures can be produced, and the accompanying illustrations show the kind of results obtained.



Electrostatic Dust Figures.

A number of materials in the form of powders or short pieces were tried, but the best pictures were given by fine mahogany sawdust. To obtain a picture, a glass plate having one or more pieces of tinfoil stuck upon the under-face, is supported horizontally. Sawdust or other suitable material is spread as uniformly as possible over the plate by means of a sieve or muslin bag, and the tinfoil disc or discs are charged by being connected with a Wimshurst machine in action. The plate has to be tapped to assist the arrangement of the particles, and it is necessary to put the machine out of action when the dust begins to move outwards from the tinfoil. By careful manipulation, distinct indications of the directions of electrostatic lines of force around plane conductors of different shapes, and with like and unlike charges, are produced. The pictures can be fixed by means of a thin layer of paraffin wax on the upper side of the glass plate, or they may be photographed. The two pictures here reproduced from Mr. Robertson's paper show the results obtained with a single disc and with two discs having unlike charges.

A MONOGRAPH on "After-images," by Mr. Shepherd Ivory Franz, forms a notable feature of the *Psychological Review*, iii. 2. This monograph deals, firstly, with an experimental analysis of the conditions affecting the production, the duration, the latent period, the space relations, &c., of the after-image; and, secondly, with a history of the phenomena and their relation to sensation, to imagination and to memory. The experiments described in the first portion were all made in the psychological laboratory of Columbia University, eleven advanced students being selected as subjects. Regarding the historical aspect, it would appear that while after-images have formed the subject of numerous writings dating back from Aristotle's *De Somniis*, the various theories are far from giving a complete explanation of the phenomena.

A FURTHER blow has been dealt to Euler's proof of the Binomial Theorem, by Mr. R. F. Muirhead, writing in the *Proceedings* of the Edinburgh Mathematical Society. This time it is not the omission of convergency considerations that is attacked, but the generalisation of the relation $f(m)f(n)=f(m+n)$ by the permanence of equivalent forms. Mr. Muirhead points out that the function $f(m)(1-\phi(x)\sin m\pi)+\psi(x)\sin m\pi$, where $\phi(x)$, $\psi(x)$ are any functions of $x$, is equal to $(1+x)^m$ when $m$ is a positive integer, and it would be equally valid to infer that functions of this type satisfied the Index Law for all values of $m$ and $n$, which is obviously false for most forms of $\phi(x)$ and $\psi(x)$.

MR. CHARLES S. SCHLICHTER has published, in the nineteenth annual report of the United States Geological Survey, Part ii., a theoretical investigation of the motion of ground waters. In it he investigates the laws of motion of water through the interspaces of an agglomeration of equal spheres, and also discusses the general laws of flow of ground waters. In connection with the motion in horizontal planes, the well-known transformations by conjugate functions are applicable; while the lines of flow in problems relating to the mutual interference of two or more wells are closely analogous to the corresponding lines in two-dimensional hydrodynamical problems involving sources and sinks. The applications of known methods of mathematical analysis to the present problem might with advantage be studied to a greater extent than is done at present.

A GUIDE to the Collection of Scottish Agates in the Edinburgh Museum of Science and Art has been prepared by Mr. J. G. Goodchild. The collection was formed by the late Prof. Heddle, whose explanatory notes on the specimens have been incorporated in the descriptions now given by Mr. Goodchild.

DR. HENRY CHARLES LANG, well known as the author of "The Butterflies of Europe," is bringing out a series of articles in *Science Gossip* on "Butterflies of the Palæarctic Region." The article in the September number deals with the genus Papilio, and is illustrated by fine photographs of *P. machaon*, var. *sphyrus*, Hb., *P. xuthus*, L., type and variety *xuthulus*, Brem., and *P. maackii*, Niéu.

THE *Archives of the Roentgen Ray*—the only journal in which the transactions of the Röntgen Society of London are officially reported—has become an indispensable quarterly for all who are interested in the development of radiography, more especially in relation to medicine. The two numbers (vol. iii. No. 4, and vol. iv. No. 1), just received, contain several excellent reproductions of Röntgen-ray photographs, as well as descriptive text referring to them, and notes and articles on recent researches.

AN illustrated price list of chemical apparatus has been received from Messrs. Brewster, Smith, and Co. Instruments and accessories for all branches of experimental and analytical chemistry appear to be included in the catalogue. With the list we have received a description of a simple spring balance—Moore's Hydrostatic Balance—arranged to illustrate the principle of Archimedes, and specific gravity. The balance should be of service to teachers of the rudiments of physics.

A GLANCE through a catalogue of Röntgen ray apparatus, just issued by the firm of Mr. H. W. Cox, Ltd., shows that the apparatus now available is of a very efficient and compact character. The instruments required to produce successful Röntgen ray pictures are so easily manipulated, and can be obtained at so reasonable a price, that there seems no reason why

every surgeon should not regard an induction coil and accessories as an indispensable part of his general outfit. A noteworthy feature of Mr. Cox's catalogue is a section in which the principles of construction of induction coils are described, and the best methods of using the apparatus explained.

THE Cambridge University Press have issued the following list of additional errata for Lord Kelvin's "Mathematical and Physical Papers," vol. iii.:—Page 33, line 8, for "21,000,000" read "2.100,000"; p. 68, in heading of Table II., for "289°" read "288°"; p. 74, line 7, for "640" read "64"; p. 173, line 6, for "the" (before "quantity") read "a"; p. 226, value of diffusivity of *wood* (col. 4) should be "·0013" instead of "·013"; p. 228, footnote, after "XCVI." insert "Part II."; p 252, line 17, before "being" insert "the whole"; p. 256, line 18, insert parenthesis marks before "since" and after "$\frac{T}{274}$"; p. 348, line 8 from foot, for "$10^{-1}$" read "$10^{-19}$": line 5 from foot, for "second" read "century"; p. 396, line 8 from foot, insert "half" after "than"; p. 398, line 3 of footnote, for "præcendentium" read "præcedentium"; p. 401, footnote, delete "or oblong-rectangle-based"; p. 403, line 25, for "§ 52" read "§ 53"; p. 409, line 5 from foot, for "Caignard" read "Cagniard"; p. 441, line 4, for "$n$" read "$q$": line 8, for "$n^2$" read "$q^2$"; p. 442, line 10 from foot, for "$2\theta$" read "$4\theta$": line 2 from foot, for "$2n$" read "$4n$"; p. 451, line 13, for "forces" read "force"; p. 459, line 5, for "forcives" (first) read "forcive"; p. 478, line 5 of footnote, delete comma after "force"; p. 479, line 8, for "15" read "12": line 9, for "·18" read "·225"; p. 480, line 16, for "of" (after "law") read "if"; p. 483, line 7, for "·18" read "·225."

THE additions to the Zoological Society's Gardens during the past week include a Rhesus Monkey (*Macacus rhesus*) from India, presented by Mr. E. G. Mills; a Short-tailed Vole (*Arvicola agrestis*, var.), British, presented by Mr. A. Thomas; a Leadbeater's Cockatoo (*Cacatua leadbeateri*) from Australia, presented by Lieut.-Colonel G. E. E. Blunt; a Laughing Kingfisher (*Dacelo gigantea*), presented by Mr. Thomas A. de Wolf; eleven Long-nosed Crocodiles (*Crocodilus cataphractus*) from Assay, South Nigeria, presented by Mr. W. J. Bowker; a West African Python (*Python sebae*) from West Africa, presented by Mr. J. S. Budgett; two One-wattled Cassowaries (*Casuarius uniappendiculatus*), a Blue-necked Cassowary (*Casuarius intensus*) from New Guinea, a Little Rock Wallaby (*Petrogale concinna*), two Regent Birds (*Sericulus melinus*) from Australia, a Ring-necked Parrakeet (*Palaeornis torquata*, var.) from India, a Serrated Terrapin (*Chrysemys scripta*) from North America, a Grooved Tortoise (*Testudo calcarata*) from South Africa, deposited.

On the 20th the comet ceases to move eastward, and commences to travel in a north-westerly path through Perseus.

VANADIUM IN METEORITES.—In a paper contributed to *Mem. Soc. Degli. Spett. Ital.* (vol. xxviii. pp. 113–119), M. M. B. Hasselberg gives the results of an extensive investigation he has been making into the constitution of meteorites. Thirty-one different specimens have been examined, and photographs taken of their spectra when volatilised in the electric arc, the region extending from λ 4268·78 to λ 4444·40. Tables are given showing the relative intensities of the characteristic vanadium lines, the discussion of which leads the author to give the following conclusions:—

(1) The quantity of vanadium present in meteorites is exceedingly small, but the sensible differences found in the several specimens leave no doubt of the reality of its presence. The meteorites of New Concord, Lundsgården, l'Aigle, Kniahynia and Alfianello are cited as showing the metal most easily.

(2) There is a distinct difference between *iron meteorites* and *stony meteorites*, the former containing *no trace* of vanadium, while the latter generally contain it in greater or less quantity.

(3) In the meso-siderites, of intermediate composition, the presence of vanadium is very doubtful, though faint indications are often found.

With regard to the Nejed and Obernkirchen meteorites, which are ferro-siderites, the author states that he has specially looked for the lines found by Lockyer at λλ 4112·5–4119·6, but without success, his vanadium spectrum not containing lines of these wave-lengths. Measures of photographs of comparison spectra of vanadium and Nejed meteorite fail to show the lines, and he gives a list of nine vanadium lines in this region which do not appear in the meteorite, and therefore is led to regard these two as not being exceptions to the rule that iron meteorites contain no trace of vanadium.

CORDOBA PHOTOGRAPHS OF STAR-CLUSTERS.—We have recently received from Dr. S. C. Chandler a volume entitled "Cordoba Photographs," containing the measures and computations made by the late Dr. B. A. Gould, from the photographs of star-clusters obtained at the Argentine National Observatory. Dr. Gould commenced the undertaking in 1872, at the Cordoba Observatory, which was placed at his disposal by the Argentine Government. After his death in 1896 the remaining portions were completed by his assistant, Mr. G. E. Whitaker, who had worked with Dr. Gould for eleven years. The volume is printed in duplicate throughout, in Spanish and English. In the first 41 pages a detailed description is given of the origin of the work, and the method of carrying it out, with full particulars and explanation of the methods of measurement and computation adopted.

Two series of photographs were obtained, one with an object-glass formerly the property of Mr. Rutherford, of 28·6 cm. aperture, and the other with a new glass constructed by Fitz, under Rutherford's superintendence. On Dr. Gould's return to New York in 1885 he had over 1200 plates, besides those of the moon, planets, comets, &c. Of these 281 were fully measured, giving the positions of over 11,000 stars. In addition 315 plates of 96 double stars have also been measured. The material thus made available was so great that it was decided to add no new measures, but proceed with the computations. For this Dr. Gould devised methods of applying corrections for calibration of the micrometer scale, expansion-coefficients of the glass plates, and the reduction of the measures to rectangular coordinates.

The star clusters are restricted to the Southern Hemisphere with only two exceptions, *Pleiades* and *Praesepe*. Each plate was obtained by exposing first for eight minutes, then moving the telescope slightly in R.A. without jar, after which a second exposure of eight minutes was given. Finally the stars were allowed to trail across the plate to give direction of diurnal motion. For some of the plates a third exposure was given instead of obtaining a trail. All the plates were albumenised to prevent distortion of the films, and there has been no trouble from this cause. Various electrical and other contrivances were tried with the telescope, but most of the work was directed by a heavy pendulum as governor. To explain the method of computation, the reduction of a plate of the Pleiades is given with full details of the calculations.

The remainder of the volume, pp. 50–482, consists of the final determined positions of 9144 stars in 37 clusters, each accompanied with its own chapter of explanation. There is a chart of each cluster, showing all the stars considered, to a scale of about 18″ = 1 mm.

## UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

MR. R. P. PARANJPYE, the Indian senior wrangler, has been awarded a special scholarship of 200*l*. by the Secretary of State, partly as a recognition of his remarkable and distinguished success, and partly to enable him to take the M.A. degree.

IT is announced that the annual distribution of medals and prizes obtained by the students of the Royal College of Science will take place in the lecture theatre of the Victoria and Albert Museum on Thursday, October 5, when Prof. A. W. Rücker, F.R.S., will deliver an address.

A COPY of the Calendar of the Durham College of Science, Newcastle-upon-Tyne, has been received. The college forms an important part of the University of the north of England. The degrees of Durham in science and letters and its diplomas in engineering are open to students of the college. The courses of instruction in all natural sciences and in every department of engineering are practical and complete, and the chemical, physical and engineering laboratories are well equipped. In addition to the biological laboratories at the College, a marine biological laboratory has lately been opened at Cullercoats, and by the generosity of the Northumberland Sea Fisheries Committee is available for college students. The agricultural department has been carefully organised, and has been entrusted with the scientific direction of the farm acquired for the purpose of experiment and demonstration by the County Council of Northumberland.

MANY friends of education will regret to learn of the death of Mr. Theodore Beck, principal of the Mahomedan College at Aligarh, at forty years of age. Writing to the *Times*, a friend of the late principal says:—" Men who were at Cambridge in the early eighties will remember Theodore Beck, scholar of Trinity and president of the union, as one of the most conspicuous figures in the University life of the time. He disappeared from the horizon of his English friends, as do all men who go out to India, when he accepted the post of principal in the recently founded college in Aligarh. When he landed in India in 1883 Sir Syed Ahmad was giving practical shape to that great rationalistic movement which was to regenerate the Mussulmans of India. Beck found himself thrown into the midst of a community the bulk of which was sullenly hostile to the English and all their ways. Sir Syed Ahmad saw that his people did not need to acquire the sciences of Europe alone, but also to readjust their ideals by an English standard; for such a change it was necessary not only that they should learn the matter of English text-books, but should also learn to love and admire individual Englishmen and follow them in the ordering of their lives. If Sir Syed was the founder, Theodore Beck was no less certainly the builder of the college in Aligarh and of the large hopes with which it is synonymous. It was he who gave practical form to the generous aspirations in Sir Syed's mind, and who built up the internal organisation of the college so that it has become the type of a new system of collegiate education in India."

## SCIENTIFIC SERIALS.

IN the *Journal of Botany* for August and September, Mr. W. West, jun., contributes a description of some Oscillatorioideæ from the plankton, including a new marine species, *Oscillatoria capitata*, which is figured; Mr. Spencer Le M. Moore, in Part v. of his "Alabastra diversa," describes a number of new species of flowering plants, and Dr. A. B. Rendle several new grasses from South Africa; Mr. J. W. White adds *Rubus Bucknalli*, sp.n., to the already too numerous British brambles.

THE *Journal* of the Royal Microscopical Society for August contains a continuation (Part v.) of Mr. F. W. Millett's report on the recent Foraminifera of the Malay Archipelago collected by Mr. A. Durrand, and a paper by the president, Mr. E. M. Nelson, on the evolution of the fine adjustment of the microscope, in which a new and important adjustment is described, invented by Reichert. Among the more important paragraphs in the summary of current researches relating to zoology, botany and microscopy is a description of a new electrically heated stage, also invented by Reichert.

## SOCIETIES AND ACADEMIES.

### PARIS.

Academy of Sciences, September 4.—M. Maurice Lévy in the chair.—Observations of Swift's Comet (1899 *a*), made with the large equatorial of the Bordeaux Observatory, by MM. G. Rayet and A. Féraud. The observations, twenty-one in number, extend from May 18 to July 15. The mean positions for 1899 are worked out both for the comet and comparison stars. —Remarks by the Director of the "Instituto y observatorio de Marina de San Fernando," offering facilities to astronomers wishing to observe the coming total eclipse of the sun in Spain. —Observations of the planet EP (J. Mascart, August 26, 1899), made at the Observatory of Besançon by M. Chofardet. Note by M. L. J. Gruey. The eight observations given extend from August 29 to September 1, the positions of the comparison stars and the apparent positions of the planets being given.—Observations of the Perseids made at Athens, by M. D. Eginitis.—On the surfaces of the fourth degree which admit an integral of the total differential of the first species, by Mr. Arthur Berry.—On the solidification of hydrogen, by Prof. James Dewar. A tube containing liquid hydrogen, and surrounded by another vacuum jacketed tube containing liquid hydrogen boiling in a vacuum, solidifies, the lower portion being a clear ice-like solid, the upper a solid froth. The density was found to be approximately ·086, the liquid at its boiling point being ·07. Solid hydrogen melts when the pressure of its saturated vapour amounts to 55 mm. The melting point, as determined by two gas thermometers containing hydrogen under reduced pressure, was found to be 16° above the absolute zero at 35 mm. pressure. The lowest temperature attained in these experiments was about $-259°$ C., or 14° absolute.—On the mode of growth in spirals of appendices in course of regeneration in the Arthropods, by M. Edmond Bordage.

## ECLIPSES.

*The Indian Eclipse*, 1898. Edited by E. W. Maunder, F.R.A.S. Pp. xii + 172. (London: Hazell, Watson, and Viney, 1899.)

*The Story of Eclipses.* By G. F. Chambers, F.R.A.S. Pp. viii + 259. (London: George Newnes, 1899.)

NOTWITHSTANDING the fact that the totally eclipsed sun can only be observed for something like three hours in a century, an extensive literature dealing with the phenomena has come into existence. Two distinct branches of the subject may be recognised—one referring chiefly to past eclipses, which have their principal use in chronology, and the other bearing upon the more recent eclipses, in which attempts to extend our knowledge of the sun itself have taken the place of superstitious fear. Of the two books named above, the first belongs to the latter category, while the other is apparently intended to give a simple survey of the whole subject.

The first book forms the report of the two expeditions organised by the British Astronomical Association to observe the total eclipse of January 22, 1898, and gives an account of the objects and results of the observations made. The organisation of the expedition, combining science with pleasure, appears to have been in capable hands, and the Association is to be congratulated on the fact that some of those who took part in the observations gave the first place to science. Mr. Maunder's party at Talni was especially active, but Mr. Bacon's party appears to have arrived at Buxar too late to undertake anything very serious. The duplication of results, which inevitably followed from the fact that the eclipse was well visible to observers all along the line, to a certain extent reduces the value of the work at any particular station, each party probably being able to claim but little in the way of novel results which would not otherwise have been brought to light. Thus it is that the more specially valuable results of these expeditions are those obtained by Mr. Evershed and Mrs. Maunder—the former with the ultra-violet region of his photographs of the so-called "flash" and coronal spectra, and the latter indicating the best means of photographing the long extensions of the corona. Miscellaneous observations of the usual character are included in the report, as well as a chapter of hints for future work. No effort has been spared to make the report attractive; the general story of the expeditions forms very interesting reading, and the explanatory matter is very clear and concise, while the numerous illustrations from photographs—not all of scientific value, however—are beautifully reproduced. The chief scientific interest undoubtedly belongs to Mr. Evershed's fine photographs, taken with a very modest prismatic camera, and the full discussion of these wlll doubtless yield valuable results.

Mr. Chambers's book has been written primarily for the benefit of the English-speaking people who may expect to witness the phenomena of the total eclipse of May 28, 1900, in Spain or the United States. A very small part, however, is given to the information which seems to us what the average probable observer will desire to know the greater part of the book being a sort of descriptive catalogue of eclipses, ancient and modern, including lunar eclipses. A complete want of proportion is, in fact, shown throughout; for instance, more than a dozen pages are taken up by an attempt to prove that the backward motion of the shadow on the dial of Ahaz was caused by a partial eclipse, while only two pages are given to the three important eclipses of 1893, 1896, and 1898. The author appears to have entirely failed to grasp the enormous advances which have lately been made, and leaves his readers in complete ignorance of the more important observations which now occupy the attention of astronomers during eclipses; thus, less than a single page is occupied by references to the spectroscope, and most of the statements made are now known to be erroneous. Finally, in his desire to satisfy the thirst for knowledge which it is one of the main objects of this series of books to create, the author refers almost entirely to works which comparatively few will be able to read, and quite omits to mention even the late Mr. Ranyard's classical compilation. The only redeeming features of the book, bearing in mind its more particular aim, are the thirty-three pages of matter describing the general phenomena of a total eclipse, and the appendix indicating how one may get to Spain or Portugal for the next eclipse.

## A FRENCH WRITER ON CLASSIFICATION.

*Aperçus de Taxinomie Générale.* Par J.-P. Durand (de Gros). Pp. 265. (Paris: Félix Alcan, 1899.)

EVERY scientific worker who takes in hand the task of classifying the objects of his study comes thereby into relation with the domain of logic and metaphysics. Whether this be done consciously or unconsciously, the classifier cannot avoid raising and dealing with questions which are the concern of philosophy as well as of physical science. The author of the book before us, starting from the position that all taxinomy (which form he prefers, on etymological grounds, to the more usual "taxonomy") must conform to logical requirements, proceeds to give a careful and elaborate analysis of the principles of logical division so far as they are involved in the classifications of science. To this he adds a free criticism, mainly from the logical point of view, of the labours of scientific taxinomists; and in the last place he furnishes some suggestions for the guidance of future workers in the same field. His preliminary analysis, if not very profound in its reasoning, is marked by the lucidity and good sense so constantly to be met with in writers of his nation. It does not add very much, except in clearness and fulness of treatment, to what is to be found in most standard works on logic, nor does it always avoid insisting at considerable length on the trite and obvious. This, however, evidently arises from the anxiety of the author to make himself thoroughly understood, and to allow no omission or ambiguity in the steps of his argument. He has certainly succeeded in expressing himself so clearly that whatever may be thought of his doctrine, no mistake can arise as to his meaning.

With regard to the critical portion of the work, it must be granted that most of the author's strictures are, from his own point of view, well founded. Nevertheless, it may be questioned whether the logical blots he contrives to hit

in the work of Mill, Littré, Bichat and others, have really the grave importance or have produced the disastrous results which he attributes to them. Mill's use of certain terms, such as "abstract" and "concrete general," is no doubt open to serious objection; but there is much likelihood that his conceptions on these points did not really differ from those of his critic; and the same *mutatis mutandis* may probably be said of the logical slips of Bichat and Haeckel. It would be unfair to accuse the author of pedantry, but at the same time it is not certain that he allows sufficiently for that faculty of the human mind which frequently leads it to conclusions practically sound by processes that are logically quite indefensible.

The constructive part of the book is hardly so strong as the critical. Here, however, M. Durand does excellent service in emphasising the point, even now imperfectly grasped by many systematists, that no classification of organisms can be really natural unless it proceeds on a phylogenetic basis. Where the phylogeny is unknown, a natural classification is so far impossible. In such cases an artificial classification, based on characters more or less arbitrarily selected, may be provisionally adopted as a substitute; and, so long as it is not treated as final, may answer all ordinary purposes without detriment to the advance of knowledge. From failure to recognise the practical value of such temporary expedients, M. Durand, as it seems to us, is led to adopt an unduly pessimistic tone with regard to he future of biological taxinomy. For a long time to come zoologists and botanists will doubtless have to proceed by the method of successive approximation; and even if the ideal result should be finally unattainable, enough will probably be gained to satisfy all demands but those of the logical purist.

M. Durand's able and acute commentary may be studied with profit by all who engage in taxinomic work themselves, or who wish to appreciate that of others The most serious charge we have to bring against him is that of making scientific molehills into logical and metaphysical mountains. F. A. D.

## OUR BOOK SHELF.

*Die Welt als That. Umrisse einer Weltansicht auf naturwissenschaftlichen Grundlage.* By J. Reinke. Pp. iv + 483. (Berlin: Gebrüder Paetel, 1899.)

IN this work Prof. Reinke sets forth his philosophic and scientific creed, his conceptions of nature and the universe, of plant, beast, man, and God. The book is divided into five parts. The first is entitled "Subject and Object of the Study of Nature," and discusses things and ideas, time and space, causality, chance, intelligence, and other metaphysical questions. The second part, under the heading of "The World-Stage," deals with the material universe and with the conceptions of matter, force and direction. The third part discusses "The Nature of Life," and in thirteen chapters treats of the cell, irritability, reproduction and heredity, adaptations, the origin of life, and kindred problems. In the fourth part, "Darwinism," the author, after giving an outline of the theory of natural selection and of the views of Nägeli and Weismann, states his own conclusions with regard to this subject. The fifth part, entitled "Natural Science and the Conception of God," discusses monism and dualism, theism, pantheism and atheism, and the first chapter of Genesis.

It is clear, from this brief summary of the contents of the book, that the field covered by it is a wide one. It must suffice here, therefore, to draw attention to the main results or conclusions reached by the author, which are in reality summed up in the last sentence of the book—"Im Anfang war die That"—"In the Beginning was the Deed." The solution to each and all of the great mysteries of science is to be found in the direct creative act of an intelligent being. One such act and deed created the material universe. A second gave rise to the first living organic substance, to protoplasm, where previously only the inorganic had existed. And a third act seems to be necessary to explain the origin of intelligence; "that matter thinks is certainly something other than that matter assimilates and breathes." These alleged creative acts are compared to the Days of Creation of the Mosaic Cosmogony, which the author considers "one of the greatest intellectual feats of history," combining both truth and poetry. As a proof of the greatness of Moses, the reader is referred to his statue at Rome by Michael Angelo, "since only one of the greatest of the mortal race of men could inspire the great artist of the Renaissance to such a work."

Prof. Reinke does not, it will be seen, arrive at very strikingly original conclusions, but it is something of a novelty to see a scientific man at the present day putting forward such propositions as the last message of science. He is frankly a dualist and considers monism "an exploded attempt to comprehend the world," the outcome of the natural effort of thinking man "to refer all explanations of things to the simplest possible principles." It is not, however, necessary to seek for unity; "the limit to be attained may just as well be duality, trinity, or a higher multiplicity." Dualism is "the ripe fruit of the studies set forth in this book." "In nature intelligent forces are to be distinguished as dominant from energetic forces as subservient; in organisms both are inseparably combined." Those who may wish for further information as to the processes of reasoning by which the author arrives at these conclusions must be referred to the work itself. E. A. M.

*La Liquéfaction aes Gaz: Méthodes nouvelles—Applications.* Par J. Cauro, Docteur ès Sciences. Pp. 83 (Paris: Gauthier-Villars, 1899.)

DR. CAURO'S book is good enough to make one wish it were better. Its chief faults are negative, and may be summed up in the words excessive concentration. When it is stated that within the limits of eighty pages the author gives an analysis of the theory of refrigeration and the changes of physical state involved, a description of the methods and apparatus of scientific investigators and of the machines employed in industrial work, a historical *résumé* of the progress of this branch of knowledge, and a review of the actual and possible applications of cold, it will be easily imagined that most of the work must be too sketchy to be of real use to any one. If refrigeration were recognised as a special subject in the examinations for some degree, Dr. Cauro's work is sufficiently accurate and up to date to make it a very good book for getting up the subject, though even from this point of view excessive brevity has led to some errors, as when the apparatus figured on p. 24 is described as a modification of that on p. 23, whereas it depends on a radically different process for attaining the same end. For popular reading, both the descriptive and the historical parts are too brief to be interesting, and are not even intelligible without more knowledge than such reading implies. Practical men of science, and practical makers of industrial machines, would have found the book very useful in reminding and suggesting, if every statement and description had been accompanied by full references to the original papers and other sources of information, so that those who are interested in any

special branch of the subject would have had a guide to full and intelligible records of detail. Such references are nowhere given. The book is worth the extra clerical work that their insertion would have involved; but as it stands it is of little use to any one. Who, for instance, is helped by this brief paragraph on p. 64?—"Concentration of sea-water.—The process is employed in some northern salt-works, and is more economical than concentration by heat."

## LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

### Movement of Sea-Gulls with a Coming Change of Weather.

IN your issue of September 7, p. 439, I read with some interest the note by Prince Kropotkin on the movements of sea-gulls upon our coasts having some connection with a coming change of weather; and that at Margate on Saturday, August 26, it was noticed such a movement was going on, the gulls passing from west of that place to the south coast, to meet, as the fishermen say, a south-west wind. It may be of interest, and as in a measure confirmatory of such a movement going on just before a marked change of weather conditions, that on Sunday evening at 5.30 o'clock six large sea-gulls passed over this place, 400 feet above the sea (situated 2½ miles due east of Cranleigh), flying in a direction south-west by south. We very seldom see gulls so far inland, but I have seen them before flying in much the same course. The direction in which these were heading would have taken them to the coast near Portsmouth, distant about thirty-five miles; and at the elevation at which they were flying, the English Channel was no doubt visible to them, for the South Downs were at the time particularly clear.

H. H. GODWIN-AUSTEN.

Nore, Hascombe, Godalming, September 12.

### Thermometric Scales for Meteorological Use.

As Mr. Buchanan has called attention to the advantages of the Fahrenheit thermometric scale as compared with the Centigrade, I will state that at the Blue Hill Meteorological Observatory, while the metric system has been adopted for research work the Fahrenheit thermometer has been retained. The chief reason is the same as that given by Mr. Buchanan, namely, the occurrence of the zero in such a place as to make nearly half the readings below zero. The reading of the scale first upward and then downward is awkward, and the averaging of the results troublesome, besides making in each case a source of error. If the Centigrade thermometer is ever adopted by the English-speaking nations, I would suggest that, at least for meteorological uses, the freezing point of water be marked 273° on the scale, and the boiling point 373°. This would give meteorologists at once the temperatures which are concerned in the change of volume of gases, and embodied in a large number of the formulas used in meteorological work. At the same time it would for ever get rid of the troublesome inverted scale. In printing the results, 200 could be put at the top of the printed column, and the excess over 200 be printed at its proper place in the column. In this way most of the observed temperatures could be expressed in whole degrees by two figures as at present.

The metric system will soon be adopted, I trust, by all the English-speaking peoples. Besides the advantages of the relations of all the different portions of the system to each other, and the ease of converting smaller measures into fractions of larger measures of the same kind, every one must recognise the advantage of having one uniform system of measurement throughout the world. Almost every civilised nation except those speaking English have now adopted the metric system, and I cannot believe the English will long hold aloof.

H. HELM CLAYTON.

Blue Hill Meteorological Observatory, September 5.

## THE NEW LUNAR PHOTOGRAPHIC ATLAS

MM. LŒWY and Puiseux have recently communicated to the Paris Academy of Sciences[1] continuations of their valuable descriptions of the unequalled lunar photographs they are now obtaining by means of the large Equatorial Coudé. As in the case of the three Parts of the Atlas already published, they accompany their descriptions with a discussion of the bearings of the new results obtained on the general questions of selenology. We have on previous occasions given an account of Parts i.,[2] ii.,[3] and iii.,[4] and we now give a full translation of the recent communications.

The first, which deals with the description of the photographs contained in the fourth Part, runs as follows:—

The fourth Part comprises, like the preceding ones, a positive on the scale of the original negative, and six enlargements on different scales. All these photographs, except one, deal with the waning moon, and for the first time we see the eastern edge illuminated to a certain extent. We propose to briefly indicate the most striking characteristics of the regions represented.

Plate *d* is a general photograph, in which nearly two-thirds of the visible hemisphere is illuminated, and distinguishes itself at first sight from similar positives already published. Here the work of reproduction has been directed in such a manner as to give, as far as possible, the details contained in the most brilliant parts of the lunar disc. But we also establish an intrinsic difference between the eastern and western halves of the moon, so far as the distribution of mountains and plains is concerned. Up to now we have seen the seas presenting themselves like a chain of circular basins, occupying only a zone of ordinary size on both sides of a great circle; they now take a sudden and considerable development in the direction of latitude. It appears that a large depression encountered the first, like the Atlantic Ocean across the Mediterranean deeps of our globe. These depressed parts, generally of sombre colour, are not of a uniform shade, and the darkest spots accumulate near the mountainous border. There is cause to consider these regions as more depressed than the neighbouring parts of the seas, and their distribution, as they are indicated in Plates *b* and *d*, is in accordance with what we know of the ways of the submarine depths on the terrestrial globe.

We have already noted, with regard to the third Part, the white borders which encircle Kepler and Copernicus, and which prolong themselves in different directions in long rectilinear streams. We find them here again illuminated more normally, and detaching themselves in consequence in a clearer manner. The systems of Euclid, Aristarchus, Olbers, Byrgius and Tycho, equally visible on Plate *d*, appear to us to be, like the first, depositories of volcanic cinders, carried to great heights by violent eruptions and disseminated by variable atmospheric currents. They imply with no less clearness different periods of activity, separated by intervals of repose. All the walled plains which serve as origin to a collection of such trails show under an oblique illumination a fairly equal uniform wall of some altitude. So soon as the sun has risen a little on their horizon, they shine with an intense whiteness, sometimes accentuated by the presence of a dark areola at the source of the trails. The great dimensions of Copernicus reveal other interesting facts; thus we see that the white tint is far from being equally distributed on the whole length of the walled plain, that the diameter of this surpasses by a great deal the length of the trails, and

[1] *Comptes rendus*, June 26 and July 3.
[2] NATURE, vol. lii. p. 435, 1895.
[3] *Ibid.*, vol. lvi. p. 280, 1897.
[4] *Ibid.*, vol. lix. p. 304, 1899.

that the latter are more often directed tangentially to the rampart than in a line with the centre. All these circumstances tend to make one consider the little orifices situated either on the central mass, on the ridge which limits the walled plain, or in the immediate neighbourhood, as the real seat of eruptive activity, which one might have been tempted to attribute to the orifice itself.

Plate XVIII., which comprises the southern pole, gives us a contour deformed by important excrescences. The Tycho region shows itself, at the setting as well as at the rising of the sun, rich in prominent ridges, which serve as limits to the walled plains they meet, and impose on them polygonal or elongated forms. A more attentive examination shows the existence of two superposed systems of parallel ridges, which cut the surface up into quadrilaterals. The influence of these alignments has made itself felt, not only in the primitive formation of the walled plains, but in the successive annexations which have often constituted a new wall, at some distance behind the first, as can be seen in Clavius. No trace of these angular fashions are to be found in the little parasite orifices, of recent date, which uniformly tend towards the perfect circle. Blancanus, without approaching the extent of Clavius, is classed with it by its clearness, its great depth, by the indented shadow which reproduces inequalities of the crest, and would lend itself admirably to measurements of altitude. In spite of the great differences of level noted, this region is very uniform in tint. This characteristic is due to the white colour which the Tycho trails throw over the whole.

Taken from the same cliché as the preceding one, Plate XIX. offers quite another aspect. We see plains prevailing here, sprinkled with islands and brilliant craters, furrowed with prominent veins or crevasses, and covered in certain parts by large trails which emanate from Copernicus and Tycho. We have already become familiar with this region in Plate VIII. of the Atlas. The comparison of the photographs dealing with very different phases is instructive. We note again the relative permanency of the bright areolæ, and the periodic variabiliy of the dark spots. The phenomenon of the encroachment on and of the submersion and final destruction of the walled plains can be observed here in all its degrees, and we meet with many cases where the depression has engulfed a half of the enclosure and the interior plain without affecting the rest of the rampart, or even the central crater.

Plate XX. takes us back again to the western hemisphere, to a part where the relief shows itself with extreme energy. Numerous local sinkings have here reduced the capacity of the crust, without its having to submit (to follow the contraction of the liquid centre) to a general sinking, accompanied by submersion. Various indications prove, however, that a movement of this sort has been begun. Thus, the great fracture of the Altai mountains, visible near the western edge of the photograph, skirts at a distance the sea of Nectar, and seems to prepare for its extension.

Another depressed space, also very vast, occupies the central part of the photograph, but has not succeeded in defining its contour, nor in determining the appearance of a sea. Most of the walled plains involved in this movement have amongst them a very marked family likeness, with a flat bottom and regular rampart. Those which have remained outside have kept their primitive physiognomy better, and retained in a great number of cases their central craters. Apart from these lines of circular depression, we see certain rectilinear tracts of primitive rocks extending over great stretches. As elevations they have formed an obstacle to the expansion of the walled plains. As depressions they have, on the contrary, made it easier, and many of them have transformed themselves into regular chaplets of small craters.

Plate XXI. conducts one still further west, up to the illuminated edge of the moon. The characteristics already verified in the Mare Humorum reappear in the Mare Crisium in a perhaps more accentuated degree; there are rarity of irregularities on the interior plains, elevation and regularity of the wall, persistence of a concentric terrace remaining adherent to the edge, accumulation of dark spots near the periphery. Quite near, the Mare Fecunditatis shows, besides its network of prominent ridges, large undulations of a rather convex character, like those of terrestrial seas. The intermediate plateaus, poor in walled plains, seem to be the fairly well preserved testimony of an ancient period. In the neighbourhood of Taruntius it presents a smooth region, probably levelled by an abundant volcanic deposit. Everywhere else it is furrowed with deep valleys, which tend to orient themselves along the meridian, and this direction seems to impose itself more and more on approaching the illuminated edge. A double system of alignments, cutting each other almost at right angles, prevails in the Pyrenees, which form the terminator at the upper part of the photograph, and Pétavius reveals itself, as well as many other walled plains of the first order, inscribed in a quadrilateral. Nearer the equator, Langrenus, with its double central mountain, its concentric terraces, its divergent trails, affords a quantity of eruptive characteristics which Copernicus and Tycho perhaps alone reunite in the same degree.

Collected on the next photograph (Pl. XXII.) we find, in a very limited space, five remarkable specimens of the great crevasses of the crust, that of Sabine, Sosigenes, Pliny, Ariadæus and Hyginus. The first three follow more or less the borders of a sea, and may be considered as separating a depressed region from the strip which has remained adherent to the mountainous plateau. The fissure of Ariadæus, prolonged a great stretch without regard to the relief of the surface, cutting many transversal chains, appears to date from an epoch when the crust was still disjoined and mobile in the tangential direction.

Hyginus presents, besides, quite a series of circular enlargements, which transform, as it were, a crevasse into a chaplet of craters.

The plain which surrounds Arago contains two characteristic examples of formations extremely rare at the present time. They are vast intumescences, 15 km. to 20 km. in size, in which the sinking of the central part would give rise to the ordinary physiognomy of the walled plains.

The last sheet may be recommended as illustrating well the structure of the mountainous masses of the moon, saved by some means, and left in relief after the formation of the seas.

Draughtsmen have had to content themselves here, in presence of the multitude of details, and of their variability of aspect, with a conventional figuration, where few objects, except those which form projections, could be named or identified. Our photograph renders a much more precise topographic description possible. The most peaked part of the Apennines and the Alps show a number of summits which can be recognised on the sheets of the preceding Parts, in spite of the change of incidence of the light. We see a characteristic appearing, noted by geographers as special to chains of the most recently elevated mountains, where the erosion has not had time to destroy the primitive constitution; it is a marked dissymmetry in the relief, throwing the highest summits to one side, and dividing the mass into two parts of very unequal average slopes.

So much for the descriptive matter. We now come to

the second communication to the Academy, which deals with the conclusions which the authors base on the photographs.

(1) There exists, from the point of view of relief, a general similarity between the seas of the moon and the plateaus which are covered to-day by terrestrial oceans.

In these, convex surfaces are more frequent than concave basins, thrown back generally towards the limit of the depressed space. In the same way, the seas of the moon present, generally at the edges, rather pronounced depressions. In one case, as in the other, we observe normal deformations of a shrinking globe shielded from the erosive action of rain, which tends, on the contrary, in all the abundantly watered parts of the earth to make the concave surfaces predominate. The explanation of this structure, such as is admitted to-day by geologists, seems to us equally valid for the moon.

(2) In order to find an equivalent resemblance in the raised parts of the surface, one ought to be able to establish on the moon features effaced by the volcanic eruptions, on the earth those which have disappeared by erosion. We can supply this in a certain measure by comparing on the one side the lunar ranges relatively poor in walled-plains, on the other by terrestrial ranges of recent elevation, where the initial structure can be reconstituted without too much effort. We then observe, on the chains which surround the lunar seas, as on those which enclose the Mediterranean basin, the contrast of a rapid interior slope and of a slightly inclined exterior one. This contrast is often so clear on the moon, that the cause may be put down to a rupture of the strata, without waiting for any stratigraphical confirmation, which up to the present time has not been realised.

(3) The greater development in the seas of the eastern half of the lunar disc shows that the phenomena of depression must have manifested themselves at an earlier period than in the western part. If it were so, one must hold that the crust had there imprisoned gases in relatively greater quantities, and opposed a smaller resistance to their expansion. It is, in fact, on the east side that the isolated orifices show themselves in greater numbers on the surface of the seas, and that the volcanic forces have created radial systems stretching in all directions.

The development of these phenomena has necessarily required a considerable time, and there is reason to admit that these plains, solidified before those of the western part of the moon, have long ago reached a configuration little different from that which they possess to-day.

(4) The formation of the seas begins by the sinking of a vast region, which is soon isolated by a circular fracture. This fracture does not generally mark the future limit of the sea. We can mention cases where the depressed space entirely escapes submersion; others where the central part only is invaded; others, finally, where the primitive enclosure is covered, and where the sea increases by annexing marginal belts. It is by a series of analogous stages that the largest walled-plains seem to have arrived at their actual dimensions.

(5) The epoch of the solidification of a sea does not coincide with that of the positive fixing of the level in the central part. This may lower itself still more, and determine by its retreat the formation of a new crevasse, parallel like the first, to the borders of the sea.

(6) The new photographs, as well as the first, furnish us with several specimens of great walled-plains where the solidification, due to the progressive cooling, has been effected at three or even four different levels, separated by intervals of several kilometres. The modern depressions, compared with the ancient ones, are nearly always less extensive, and have a more rapid interior slope and a more regular circular form. The more modern ones, such as those which open on the bottom of Longomontanus already very depressed, present no trace of the surrounding bulge; that is to say, that their appearance does not seem to have been preceded by an upheaval.

(7) Nevertheless, this intumescence phenomenon of the lunar crust, considered by us to be the habitual preliminary of the formation of walled-plains, has in certain exceptional but well verified cases given rise to convex figures, of which the central part has not sunk.

(8) We have previously indicated how it was possible in a fairly large number of cases, to assign the relative age of the walled plains according to the state of preservation of their ramparts, and the more or less complete submersion of their interior cavity. In the parts invaded by the trails, we can judge, by another characteristic, the epoch of the interior solidification of the walled-plain. It is convenient to place in the first line and in order of age the plains which have received and retained a uniform white covering; then those which only present some feeble and late trails, in the form of bands; lastly, those which have remained completely clear, and encroach to-day by their sombre tint on the neighbouring region.

This chronological criterion, clearer than that which depends on the state of preservation of the ridges, informs us also of the relative time of solidification in the different parts of the seas. Unfortunately, it fails us in the fairly numerous regions to which the trails have not extended.

(9) In general, the great systems of trails cover indistinctly all the undulations of the soil in their path. This circumstance has already permitted us to conclude that the formidable volcanic eruptions, of which the moon has been the theatre, belong to a recent time in the history of our satellite. They must have been preceded by the almost complete solidification of the seas, and of the bottom of the walled-plains. It seems to us the same fact must be taken into consideration in the problem, so often discussed, of the atmosphere of the moon. In fact, not only have these eruptions set at liberty great quantities of gas or vapours, but the diffusion of cinders to great distances infers a gaseous envelope of a certain density.

It is true that the relative feebleness of gravity helps one to understand their initial ascent to a considerable altitude. However, the resistance of the atmosphere must have been sufficient to retard the fall of this dust during its transport over a distance of more than 1000 kilometres.

Has the time which has elapsed since the great eruptions sufficed to bring about the total disappearance of this gaseous envelope? One is inclined to doubt it, on examining the mechanism of the two principal causes which could have operated in this direction. The crust, already everywhere solidified, could only have absorbed the gases slowly and with difficulty. The loss in space of molecules with a velocity great enough to carry them into the sphere of attraction of another body became of necessity less and less in proportion as the temperature became lower. We find, therefore, in the examination of the lunar surface serious ground to believe that there exists, at the present time, a residue of atmosphere of which the detection, surrounded as it is with great difficulties, may yet be realised.

This induction adds itself to that which has been furnished, as we have seen by the discussion of eclipses and occultations. The care which astronomers have for some years given to the study of these phenomena, and the great number of occultations of small stars which may now be observed at each total eclipse, give reason to hope that this discussion may soon be resumed on a new basis, and lead to more precise conclusions.

## *THE DOVER MEETING OF THE BRITISH ASSOCIATION.*

*Dover, September* 19.

THE meeting of the British Association at Dover, which concludes this week, has been on the whole a great success, especially when the size of the town and the fact that it is the most ambitious effort the town has ever made are considered. The number of members and associates present falls little short of 1400, and amongst these are included an unusually large number of the chief representatives of science. The proceedings at the various Sections have been interesting, though there has been no very startling announcement made at any of them, but very good work has been done. Though there is, perhaps, no longer as great a necessity as formerly for the missionary side of the Association's work, yet its usefulness as a common meeting ground for representatives of science in every branch can never be overrated. The necessity for some such central gathering point as the Association affords becomes the greater as science becomes more and more specialised.

The Presidential Addresses in the various Sections have reached a very high standard of excellence. Prof. Poynting's address in Section A was a masterpiece of exposition; that of Mr. Horace Brown in Section B was remarkable for the light it throws on many of the obscure problems so interesting alike to botanists and chemists, and contained much original work. The Mechanical Science Section had a most interesting address from its President, Sir W. H. White. The Geological Section arranged to have its address on Saturday, September 16, when the French Association paid its visit to Dover. A very large gathering of a cosmopolitan character assembled to hear Prof. Geikie discourse on geological time. The vote of thanks was moved by Lord Lister and seconded by the President of the French Geological Society.

The Presidential Addresses to which reference has just been made were delivered for the most part on Thursday and Friday, arrangements being made so that no two addresses were appointed for the same time. Thus all the Sectional meetings at the time of the Presidential Addresses were well filled.

On Thursday afternoon the first social function took place in the College grounds, where the Chairman of the College Council, headmaster and master entertained over one thousand guests. The band of the Royal Artillery and the Westminster Glee Singers enlivened the proceedings. The balloon ascent did not take place owing to a high N.E. wind prevailing, which would have taken the balloon into the North Sea. On Friday, however, the wind had fallen a little, and a non-scientific balloon ascent took place. The balloon descended later on at Gravelines, and a message of greeting from the Headmaster of Dover College was delivered to the Mayor on behalf of the President of the British Association. On Friday evening a most interesting though short address was delivered by Prof. Richet, of Paris, who proved himself to be an adept both in oratory and in the art of scientific exposition. The vote of thanks was moved by Lord Lister and seconded by Sir W. T. Thiselton-Dyer in most appropriate terms. A smoking concert followed which reflected great credit on its organisers.

The reception of the members of the French Association took place on Saturday. About 280 members arrived at the Admiralty Pier about 9.30, and were received by the President of the British Association and those members who were Correspondents and Associates of the Academy of Sciences. The military were also represented at the landing on the pier. Some disappointment seems to have been felt by the spectators that a larger number of members of the British Association were not present, but this feeling was not experienced by the French visitors, who were delighted with the warmth and cordial nature of their greeting, especially when Sir Michael Foster kissed Dr. Brouardel on both cheeks. Sir Michael Foster in his speech at the luncheon wittily referred to this act as the embracing of the daughter by the mother. Seven tram cars then conveyed the members off to the Town Hall, where the Mayor of Dover, accompanied by the Corporation, officially received the visitors, and various speeches were delivered. The gathering then broke up, and various Sections were visited. At two o'clock some 800 guests sat down to an elaborate luncheon in a marquee near the reception-room. After the lunch speeches were delivered, and toasts of a most cordial nature were proposed. The Presidents of the two Associations, the Mayors of Dover and Boulogne, the Under-Secretary for War (Mr. G. Wyndham), the member for Dover, being amongst the chief speakers. Everything passed off with great cordiality and enthusiasm. After the lunch the whole assembly was photographed in the College grounds. The French visitors then paid a visit to the Castle, where they were shown the chief objects of interest by the Rev. S. P. H. Statham, Senior Chaplain to the Forces, and author of a recently published history of Dover. The visitors were taken back to Boulogne by a special steamer (the *Empress*) at six o'clock. In the evening an interesting military tattoo took place on the sea-front, which was lavishly illuminated for the occasion. On Sunday there were services at most of the Dover churches, and a large number of members of the Association visited Canterbury, where an organ recital was given in the afternoon, in addition to the special services and sermons announced for the occasion. In Dover College Chapel, the Rev. A. H. Stevens gave a very interesting and well-arranged organ recital in the afternoon also.

On Monday there was a garden-party at the Park, which attracted a large gathering of people and was a perfect success in every way. The feature of the evening was the lecture by Prof. Fleming on the centenary of the electric current, which was illustrated by numerous exceedingly interesting experiments. Prof. Fleming for a couple of hours kept his large audience listening in rapt attention to the masterly exposition of his subject. To the general public, perhaps the most interesting part was the demonstration of the Marconi wireless telegraphy, by which messages were exchanged with Dr. Brouardel and with the Goodwin Lightship.

On Wednesday there is to be a visit to Canterbury to meet one hundred members of the French Association. There will be a lunch, which will be attended by about one hundred of the leading members of the British Association, in addition to the French visitors. Previously to the visit to Canterbury, the concluding general meeting will be held, when a vote of thanks to the Mayor and Corporation for their reception of the Association will be moved by Lord Lister, and seconded by Sir Frederick Bramwell. The vote will be acknowledged by the Town Clerk on behalf of the Mayor, and by Mr. W. H. Pendlebury, who is local secretary jointly with Colonel Knocker. A second vote of thanks will be proposed to the Council and Headmaster of Dover College for their kindness in allowing the use of their rooms and the College grounds, which have added so much to the interest of the meeting. Votes of thanks will also be given to those who have offered hospitality to members of the Association, and especially to the naval and military authorities who have in various ways helped to make the meeting a success.

On Thursday, if the weather is propitious, a large number of members, including the chief representatives of the various branches of science, are expected to visit Boulogne. This will conclude the Dover meeting of the British Association, which will be looked back upon with great interest by most of those who have attended it.

The chief members of the French Association who visited Dover were Dr. Brouardel, the president; Dr. Aigre, the Mayor of Boulogne; Dr. Boushard. the ex-president; MM. Dislere, also ex-president; Gariel, secretary; Lôir (nephew of Pasteur), also secretary; M. Bergoine, Professor of Medicine at Bordeaux; M. Namy, Membre de l'Institute; M. Giard, professor at the Sorbonne; Dr. Ferraud; M. Collignon; M. Farjon; M. de Guerne, ex-president; Dr. de Walcourt; Dr. Dufour, of Lausanne, and others. It will be seen that the French visitors were representative men.

W. H. Pendlebury.

*Work of the General Committee.*

The report of the council of the Association was read and adopted at the first meeting of the general committee. It announced that after due consideration the council had resolved to recommend the general committee to contribute the sum of 1000*l*. to the National Antarctic Expedition, and that the grant be given out of the accumulated funds of the Association, and not out of the sum allocated to annual grants. The report also stated that the following resolutions, referred to the council by the general committee for consideration and action if desirable, have been considered and acted upon:—

(1) That having regard to the letter of December 15, 1897, from Sir E. Maunde Thompson, the council be requested to take further action with regard to a bureau of ethnology, by renewing the correspondence with the Trustees of the British Museum.

A committee was accordingly appointed for the purpose of conferring with the officers of the British Museum. The President has also been in correspondence with the Marquis of Salisbury regarding this matter, and the council have the pleasure to announce that satisfactory arrangements have been made for the establishment of such a bureau, and that Lord Salisbury has directed that reports prepared by officers in the various Protectorates under the administration of the Foreign Office be forwarded to the British Museum.

(2) That the council be requested to consider the desirability of representing to the Colonial Government that the early establishment of a magnetic observatory at the Cape of Good Hope would be of the highest utility to the science of terrestrial magnetism, especially in view of the Antarctic expeditions which are about to leave Europe, and that the observatory should be established at such a distance from electric railways and tramways as to avoid all possibility of disturbance from them.

The question having been considered, the council requested the President to make the necessary representation to the Colonial Government. The council have received a minute of the Government of Cape Colony, through the High Commissioner, stating that while Ministers have much sympathy with the suggestion to establish a magnetic observatory, and do not overlook the scientific and practical aspects of the project, they do not regard as practicable the immediate provision by the colony of funds for the carrying out of the scheme.

(3) That the council be requested to consider the advisability of urging Her Majesty's Government to place at the disposal of the Seismological Committee of the British Association a suitable building for the housing of apparatus for continuous seismological observations.

A committee which was appointed to report on this resolution stated that in their opinion it is desirable that a central station should be established, and recommended the council to request the Government to place a suitable building at the disposal of the Seismological Committee which could be used as a station for carrying on observations and would serve as a centre for the stations (now twenty-three in number) in various parts of the world which, at the request of the committee, have been supplied with seismographic apparatus of the pattern they have recommended.

The council decided to reappoint the committee for the purpose of reporting further on the best situation for the proposed central seismological station and on the cost of its maintenance.

(4) That the council be requested to urge strongly on the Indian Government the desirability, in the interests both of administration and of science, to promote an inquiry, under the direction of skilled anthropologists, into the physical and mental characteristics of the various races throughout the Empire, including their institutions, customs and traditions, and a carefully organised photographic survey.

A committee which was appointed to consider this question reported that in their opinion the resolution in its present form is of too comprehensive and costly a character to justify the council in submitting it to the Indian Government.

(5) That the council be recommended to issue the collected reports on the North-Western tribes of Canada in a single volume at a moderate price, reprinting so many of the reports as may be necessary.

The council resolved that the reports be not reprinted.

(6) That the council be requested to bring under the notice of the Admiralty the importance of securing systematic observations upon the erosion of the sea coast of the United Kingdom, and that the co-operation of the coastguard might be profitably secured for this purpose.

A committee having been appointed to report on the above resolution, recommended that the council inquire whether the Admiralty would be willing to arrange that observations of a simple character on changes in the sea coast be recorded and reported by the coastguards. The committee pointed out that if the Admiralty consented to carry out this proposal it would be necessary to appoint a committee for the purpose of drawing up a scheme of instruction for the observers, making arrangements for starting the work, and subsequently examining from time to time such localities as may seem to require special attention. This recommendation having been adopted by the council, the president was requested to approach the Admiralty upon the subject, and in response a reply was received from the Admiralty stating that my Lords saw no objection to this proposal, as the required observations could be made by the men in the ordinary course of their duty.

At the second meeting of the general committee invitations for the meeting of the Association in 1902 were received, and the officers were appointed for next year's meeting at Bradford, to commence on Wednesday, September 5. The meeting will be held at Glasgow in 1901. Representatives of the cities of Belfast and Cork invited the Association to meet at one of these places in 1902; but the president explained that no definite answer could yet be given to the invitations.

Upon the proposal of Lord Lister, seconded by Sir Archibald Geikie, Sir William Turner, F.R.S., was appointed President-elect for the meeting at Bradford in 1900.

Sir J. Evans proposed that the following persons be asked to serve as vice-presidents at the Bradford meeting:—The Earl of Scarborough (Lord Lieutenant of the West Riding), the Duke of Devonshire, the Marquis of Ripon, the Bishop of Ripon, Lord Masham, the Mayor of Bradford, the Hon. H. E. Butler, Sir A. Binnie, Prof. Rücker, and Prof. Thorpe.

Sir Norman Lockyer seconded the resolution, which was carried unanimously.

The general secretaries (Sir W. Roberts-Austen and Prof. Schäfer), the assistant general secretary (Mr. Griffith), and the general treasurer (Prof. Carey Foster) were re-elected.

The following is a synopsis of the grants of money made for scientific purposes by the general committee, at the meeting just concluded:—

*Mathematics.*

| | £ |
|---|---|
| *Rayleigh, Lord—Electrical Standards (£300 in hand) ... | 25 |

* Re-appointed.

## SECTION C.

GEOLOGY.

OPENING ADDRESS BY SIR ARCHIBALD GEIKIE, D.C.L., D.SC., F.R.S., PRESIDENT OF THE SECTION.

AMONG the many questions of great theoretical importance which have engaged the attention of geologists, none has in late years awakened more interest or aroused livelier controversy than that which deals with time as an element in geological history. The various schools which have successively arisen—Cataclysmal, Uniformitarian, and Evolutionist—have had each its own views as to the duration of their chronology, as well as to the operations of terrestrial energy. But though holding different opinions, they did not make these differences matter of special controversy among themselves. About thirty years ago, however, they were startled by a bold irruption into their camp from the side of physics. They were then called on to reform their ways, which were declared to be flatly opposed to the teachings of natural philosophy. Since that period the discussion then started regarding the age of the earth and the value of geological time has continued with varying animation. Evidence of the most multifarious kind has been brought forward, and arguments of widely different degrees of validity have been pressed into service both by geologists and palæontologists on one side, and by physicists on the other. For the last year or two there has been a pause in the controversy, though no general agreement has been arrived at in regard to the matters in dispute. The present interval of comparative quietude seems favourable for a dispassionate review of the debate. I propose, therefore, to take, as perhaps a not inappropriate subject on which to address geologists upon a somewhat international occasion like this present meeting of the British Association at Dover, the question of Geological Time. In offering a brief history of the discussion, I gladly avail myself of the opportunity of enforcing one of the lessons which the discussion has impressed upon my own mind, and to point a moral which, as it seems to me, we geologists may take home to ourselves from a consideration of the whole question. There is, I think, a practical outcome which may be made to issue from the controversy in a combination of sympathy and co-operation among geologists all over the world. A lasting service will be rendered to our science if by well-concerted effort we can place geological dynamics and geological chronology on a broader and firmer basis of actual experiment and measurement than has yet been laid.

To understand aright the origin and progress of the dispute regarding the value of time in geological speculation, we must take note of the attitude maintained towards this subject by some of the early fathers of the science. Among these pioneers none has left his mark more deeply graven on the foundations of modern geology than James Hutton. To him, more than to any other writer of his day, do we owe the doctrine of the high antiquity of our globe. No one before him had ever seen so clearly the abundant and impressive proofs of this remote antiquity recorded in the rocks of the earth's crust. In these rocks he traced the operation of the same slow and quiet processes which he observed to be at work at present in

* Re-appointed.

gradually transforming the face of the existing continents. When he stood face to face with the proofs of decay among the mountains, there seems to have arisen uppermost in his mind the thought of the immense succession of ages which these proofs revealed to him. His observant eye enabled him to see "the operations of the surface wasting the solid body of the globe, and to read the unmeasurable course of time that must have flowed during those amazing operations, which the vulgar do not see, and which the learned seem to see without wonder" ("Theory of the Earth," vol. i. p. 108). In contemplating the stupendous results achieved by such apparently feeble forces, Hutton felt that one great objection he had to contend with in the reception of his theory, even by the scientific men of his day, lay in the inability or unwillingness of the human mind to admit such large demands as he made on the past. "What more can we require?" he asks in summing up his conclusions; and he answers the question in these memorable words: "What more can we require? Nothing but time. It is not any part of the process that will be disputed; but after allowing all the parts, the whole will be denied; and for what?—only because we are not disposed to allow that quantity of time which the ablution of so much wasted mountain might require" (*op. cit.* vol. ii. p. 329).

Far as Hutton could follow the succession of events registered in the rocky crust of the globe, he found himself baffled by the closing in around him of that dark abysm of time into which neither eye nor imagination seemed able to penetrate. He well knew that, behind and beyond the ages recorded in the oldest of the primitive rocks, there must have stretched a vast earlier time, of which no record met his view. He did not attempt to speculate beyond the limits of his evidence. "I do not pretend," he said, "to describe the beginning of things; I take things such as I find them at present, and from these I reason with regard to that which must have been (*op. cit.* vol. i. p. 173, *note*). In vain could he look, even among the oldest formations, for any sign of the infancy of the planet. He could only detect a repeated series of similar revolutions, the oldest of which was assuredly not the first in the terrestrial history, and he concluded, as "the result of this physical inquiry, that we find no vestige of a beginning, no prospect of an end" (*op. cit.* vol. i. p. 200).

This conclusion from strictly geological evidence has been impugned from the side of physics, and, as further developed by Playfair, has been declared to be contradicted by the principles of natural philosophy. But if it be considered on the basis of the evidence on which it was originally propounded, it was absolutely true in Hutton's time and remains true to-day. That able reasoner never claimed that the earth has existed from all eternity, or that it will go on existing for ever. He admitted that it must have had a beginning, but he had been unable to find any vestige of that beginning in the structure of the planet itself. And notwithstanding all the multiplied researches of the century that has passed since the immortal "Theory of the Earth" was published, no relic of the first condition of our earth has been found. We have speculated much, indeed, on the subject, and our friends the physicists have speculated still more. Some of the speculations do not seem to me more philosophical than many of those of the older cosmogonists. As far as trustworthy evidence can be drawn from the rocks of the globe itself, we do not seem to be nearer the discovery of the beginning than Hutton was. The most ancient rocks that can be reached are demonstrably not the first-formed of all. They were preceded by others which we know must have existed, though no vestige of them may remain.

It may be further asserted that, while it was Hutton who first impressed on modern geology the conviction that for the adequate comprehension of the past history of the earth vast periods of time must be admitted to have elapsed, our debt of obligation to him is increased by the genius with which he linked the passage of these vast periods with the present economy of nature. He first realised the influence of time as a factor in geological dynamics, and first taught the efficacy of the quiet and unobtrusive forces of nature. His predecessors and contemporaries were never tired of invoking the more vigorous manifestations of terrestrial energy. They saw in the composition of the land and in the structure of mountains and valleys memorials of numberless convulsions and cataclysms. In Hutton's philosophy, however, "it is the little causes, long continued, which are considered as bringing about the greatest changes of the earth" ("Theory of the Earth," vol. ii. p. 205).

And yet, unlike many of those who derived their inspiration from his teaching, but pushed his tenets to extremes which he doubtless never anticipated, he did not look upon time as a kind of scientific fetich, the invocation of which would endow with efficacy even the most trifling phenomena. As if he had foreseen the use that might be made of his doctrine, he uttered this remarkable warning: "With regard to the effect of time, though the continuance of time may do much in those operations which are extremely slow, where no change, to our observation, had appeared to take place, yet, where it is not in the nature of things to produce the change in question, the unlimited course of time would be no more effectual than the moment by which we measure events in our observations" (*op. cit.* vol. i. p. 44).

We thus see that in the philosophy of Hutton, out of which so much of modern geology has been developed, the vastness of the antiquity of the globe was deduced from the structure of the terrestrial crust and the slow rate of action of the forces by which the surface of the crust is observed to be modified. But no attempt was made by him to measure that antiquity by any of the chronological standards of human contrivance. He was content to realise for himself and to impress upon others that the history of the earth could not be understood, save by the admission that it occupied prolonged though indeterminate ages in its accomplishment. And assuredly no part of his teaching has been more amply sustained by the subsequent progress of research.

Playfair, from whose admirable "Illustrations of the Huttonian Theory" most geologists have derived all that they know directly of that theory, went a little further than his friend and master in dealing with the age of the earth. Not restricting himself, as Hutton did, to the testimony of the rocks, which showed neither vestige of a beginning nor prospect of an end, he called in the evidence of the cosmos outside the limits of our planet, and declared that in the firmament also no mark could be discovered of the commencement or termination of the present order, no symptom of infancy or old age, nor any sign by which the future or past duration of the universe might be estimated ("Illustrations of the Huttonian Theory, § 118). He thus advanced beyond the strictly geological basis of reasoning, and committed himself to statements which, like some made also by Hutton, seem to have been suggested by certain deductions of the French mathematicians of his day regarding the stability of the planetary motions. His statements have been disproved by modern physics; distinct evidence, both from the earth and the cosmos, has been brought forward of progress from a beginning which can be conceived, through successive stages to an end which can be foreseen. But the disproof leaves Hutton's doctrine about the vastness of geological time exactly where it was. Surely it was no abuse of language to speak of periods as being vast, which can only be expressed in millions of years.

It is easy to understand how the Uniformitarian school, which sprang from the teaching of Hutton and Playfair, came to believe that the whole of eternity was at the disposal of geologists. In popular estimation, as the ancient science of astronomy was that of infinite distance, so the modern study of geology was the science of infinite time. It must be frankly conceded that geologists, believing themselves unfettered by any limits to their chronology, made ample use of their imagined liberty. Many of them, following the lead of Lyell, to whose writings in other respects modern geology owes so deep a debt of gratitude, became utterly reckless in their demands for time, demands which even the requirements of their own science, if they had adequately realised them, did not warrant. The older geologists had not attempted to express their vast periods in terms of years. The indefiniteness of their language fitly denoted the absence of any ascertainable limits to the successive ages with which they had to deal. And until some evidence should be discovered whereby these limits might be fixed and measured by human standards, no reproach could justly be brought against the geological terminology. It was far more philosophical to be content, in the meanwhile, with indeterminate expressions, than from data of the weakest or most speculative kind to attempt to measure geological periods by a chronology of years or centuries.

In the year 1862 a wholly new light was thrown on the question of the age of our globe and the duration of geological time by the remarkable paper on the Secular Cooling of the Earth communicated by Lord Kelvin (then Sir William Thomson) to the Royal Society of Edinburgh (*Trans. Roy. Soc. Edin.*, vol. xxiii., 1862). In this memoir he first developed his now

well-known argument from the observed rate of increase of temperature downwards from the surface of the land. He astonished geologists by announcing to them that some definite limits to the age of our planet might be ascertained, and by declaring his belief that this age must be more than 20 millions, but less than 400 millions, of years.
